MODERN TRENDS AND DEVELOPMENTS

Upper-air observations by means of balloon-borne sounding equipment. Once again technology provided the means with which to test the new scientific ideas and stimulate yet newer ones. During the late 1920s and '30s, several groups of investigators (those headed by Yrjö Väisälä of Finland and Pavel Aleksandrovich Malchanov of the Soviet Union, for example) began using small radio transmitters with balloon-borne instruments, eliminating the need to recover the instruments and speeding up access to the upper-air data. These radiosondes, as they came to be called, gave rise to the upper-air observation networks that still exist today. Approximately 75 stations in the United States and more than 500 worldwide release, twice daily, balloons that reach heights of 30,000 metres or more. Observations of temperature and relative humidity at various pressures are radioed back to the station from which the balloons are released as they ascend at a predetermined rate. The balloons also are tracked by radar in order to ascertain winds from their drift.

Use of radiosondes

Forecasters are able to produce synoptic weather maps of the upper atmosphere twice each day on the basis of radiosonde observations. While new methods of upper-air measurement have been developed, the primary synoptic clock times for producing upper-air maps are still the radiosonde-observation times—namely, 0000 (midnight) and 1200 (noon) Greenwich Mean Time (GMT). Furthermore, modern computer-based forecasts use 0000 and 1200 GMT as the starting times from which they calculate the changes that are at the heart of modern forecasts. It is, in effect, the synoptic approach carried out in a different way, intimately linked to the radiosonde networks developed during the 1930s and '40s.

Application of radar. As in many fields of endeavour, weather prediction experienced several breakthroughs during and immediately after World War II. The British

began using microwave radar in the late 1930s to monitor enemy aircraft, but it was soon learned that radar gave excellent returns from raindrops at certain wavelengths (five to 10 centimetres). As a result it became possible to track and study the evolution of individual showers or thunderstorms, as well as to "see" the precipitation structure of larger storms. Figure 64 shows an image of the rain bands (not clouds) in a hurricane.

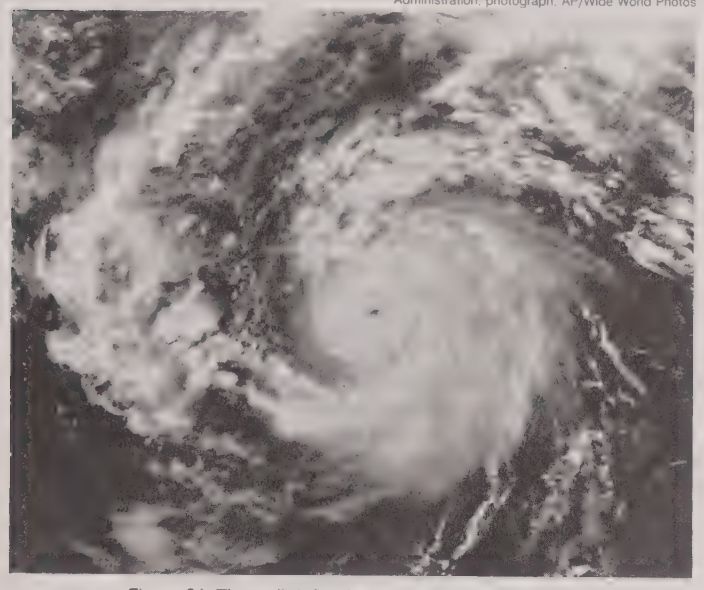

Figure 64: The well-defined eye and the rain bands of Hurricane Hyacinth about 805 kilometres (500 miles) south of the southern tip of Baja California, Mexico, photographed from an Earth-orbiting satellite on Aug. 9, 1976.

Radar surveillance of tornadoes and thunderstorms

Since its initial application in meteorological work, radar has grown as a forecaster's tool. Virtually all tornadoes and severe thunderstorms over the United States and in some other parts of the world are monitored by radar. Radar observation of the growth, motion, and characteristics of such storms provide clues as to their severity. Modern radar systems use the Doppler principle of frequency shift associated with movement toward or away from the radar transmitter/receiver to determine wind speeds as well as storm motions.

Using radar and other observations, the Japanese-American meteorologist Tetsuya T. Fujita discovered many details of severe thunderstorm behaviour and of the structure of the violent local storms common to the Midwest region of the United States. His Doppler-radar analyses of winds revealed "microburst" gusts. These gusts cause the large wind shears (differences) associated with strong rains that have been responsible for some plane crashes. Figure 65 shows how such a microburst caused the crash of an airliner at Kennedy Airport in New York on June 24, 1975.

Other types of radar have been used increasingly for detecting winds continuously, as opposed to twice a day. These wind-profiling radar systems actually pick up signals "reflected" by clear air and so can function even when no clouds or rain are present.

Meteorological measurements from satellites and aircraft. A major breakthrough in meteorological measurement came with the launching of the first meteorological satellite, the TIROS (Television and Infrared Observation Satellite), by the United States on April 1, 1960. The impact of global quantitative views of temperature, cloud, and moisture distributions, as well as of surface properties (*e.g.*, ice cover and soil moisture), has already been substantial. Furthermore, new ideas and new methods may very well make the 21st century the "age of the satellite" in weather prediction.

Medium-range forecasts that provide information five to seven days in advance were impossible before satellites began making global observations—particularly over the ocean waters of the Southern Hemisphere—routinely available in real time. Global forecasting models developed at the U.S. National Center for Atmospheric Research (NCAR), the European Centre for Medium Range Weather Forecasts (ECMWF), and the U.S. National Meteorological Center (NMC) became the standard during the 1980s, making medium-range forecasting a reality.

Meteorological satellites travel in various orbits and carry a wide variety of sensors. They are of two principal types: the low-flying polar orbiter, and the geostationary orbiter.

Polar orbiter

The first type circle the Earth at altitudes of 500–1,000 kilometres and in roughly north–south orbits. They appear overhead at any one locality twice a day and provide very high-resolution data because they fly close to the Earth. Such satellites are vitally necessary for much of Europe and other high-latitude locations because they orbit near the poles. These satellites do, however, suffer from one major limitation: they can provide a sampling of atmospheric conditions only twice daily.

The geostationary satellite is made to orbit the Earth along its equatorial plane at an altitude of about 36,000 kilometres. At that height the eastward motion of the satellite coincides exactly with the Earth's rotation, so that the satellite remains in one position above the Equator. Satellites of this type are able to provide an almost continuous view of a wide area (see above Figure 24). Because of this capability, geostationary satellites have yielded new information about the rapid changes that occur in thunderstorms, hurricanes, and certain types of fronts, making them invaluable to weather forecasting as well as meteorological research.

One weakness common to virtually all satellite-borne sensors and to some ground-based radars that use UHF/VHF waves is an inability to measure thin layers of the atmosphere. One such layer is the tropopause, the boundary between the relatively dry stratosphere and the meteorologically active layer below. This is often the region of the jet streams. Important information about these kinds of high-speed air currents is obtained with sensors mounted on high-flying commercial aircraft and is routinely included in global weather analyses.

Numerical weather prediction (NWP) models. Thinkers frequently advance ideas long before the technology exists to implement them. Few better examples exist than that of numerical weather forecasting. Instead of mental estimates or rules of thumb about the movement of storms, numerical forecasts are objective calculations of changes to the weather map based on sets of equations called models. Shortly after World War I a British scientist named Lewis F. Richardson completed such a forecast that he had been working on for years by tedious and difficult hand

From Theodore Fujita, *The Downburst* (1985)

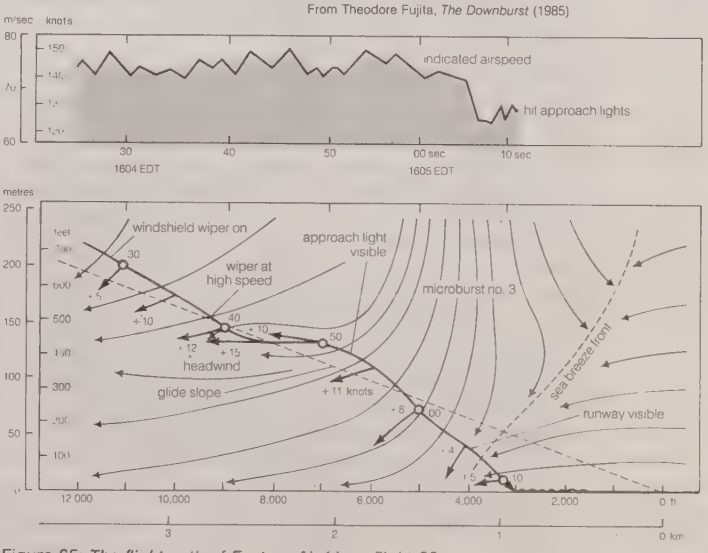

Figure 65: *The flight path of Eastern Air Lines flight 66 at Kennedy Airport, New York City, on June 24, 1975.*
The flight ended in a crash caused by "microburst" gusts, the downburst of air from a thunderstorm. As the airplane approached the downburst, the head wind lifted it above the glide slope. After the pilot corrected for this, the airplane lost the head wind and received a downward push from the downburst. Both effects pushed the airplane far below the glide slope.

calculations. Although the forecast proved to be incorrect, Richardson's general approach was accepted decades later when the electronic computer became available. In fact, it has become the basis for nearly all present-day weather forecasts. Human forecasters may interpret or even modify the results of the computer models, but there are few forecasts that do not begin with numerical-model calculations of pressure, temperature, wind, and humidity for some future time.

The method is closely related to the synoptic approach (see above). Data are collected rapidly by a Global Telecommunications System for 0000 or 1200 GMT to specify the initial conditions. The model equations are then solved for various segments of the weather map—often a global map—to calculate how much it will change in a given time, say, 10 minutes. With such changes added to the initial conditions, a new map is generated (in the computer's memory) valid for 0010 or 1210 GMT. This map is treated as a new set of initial conditions, probably not quite as accurate as the measurements for 0000 and 1200 GMT but still very accurate. A new step is undertaken to generate a forecast for 0020 or 1220. This process is repeated step after step. In principle, the process could continue indefinitely. In practice, small errors creep into the calculations, and they accumulate. Eventually, the errors become so large by this cumulative process that there is no point in continuing.

Global numerical forecasts are produced regularly (once or twice daily) at the ECMWF, the NMC, and the U.S. military facilities in Omaha, Neb., and Monterey, Calif., as well as in Tokyo, Moscow, and Melbourne. In addition, specialized numerical forecasts designed to predict more details of the weather are made for many smaller regions of the world by various national weather services, military organizations, and even a few private companies. Finally, research versions of numerical weather prediction models are constantly under review, development, and testing at NCAR and at the Goddard Space Flight Center in the United States and at universities in several nations.

The capacity and complexity of numerical weather prediction models have increased dramatically since the mid-1940s when the earliest modeling work was done by the mathematician John von Neumann and the meteorologist Jule Charney at the Institute for Advanced Study in Princeton, N.J. Because of their pioneering work and the discovery of important simplifying relationships by other scientists (notably Arnt Eliassen of Norway and Reginald Sutcliffe of Britain), a joint U.S. Weather Bureau, Navy, and Air Force numerical forecasting unit was formed in 1954 in Washington, D.C. Referred to as JNWP, this unit was charged with producing operational numerical forecasts on a daily basis.

The era of numerical weather prediction thus really began in the 1950s. As computing power grew, so did the complexity, speed, and capacity for detail of the models. And as new observations became available from such sources as Earth-orbiting satellites, radar systems, and drifting weather balloons, so too did methods sophisticated enough to ingest the data into the models as improved initial synoptic maps.

Numerical forecasts have improved steadily over the years. The vast Global Weather Experiment, first conceived by Charney, was carried out by many nations in 1979 under the leadership of the World Meteorological Organization to demonstrate what high-quality global observations could do to improve forecasting by numerical prediction models. The results of that effort continue to effect further improvement.

Mesoscale numerical prediction models

A relatively recent development has been the construction of mesoscale numerical prediction models. The prefix meso- means "middle" and here refers to middle-sized features in the atmosphere, between large cyclonic storms and individual clouds. Fronts, clusters of thunderstorms, hurricane bands, and jet streams are mesoscale structures, and their evolution and behaviour are crucial forecasting problems that only recently have been dealt with in numerical prediction. Richard A. Anthes developed a widely used American research version, the NCAR/Penn State Mesoscale Model, which shows the potential for detailed predictions of the location and evolution of structures such as fronts, rainbands, and ice storms. By the late 1980s the national weather services of several countries were producing numerical forecasts of considerable detail by means of limited-area mesoscale models.

Principles and methodology of weather forecasting

SHORT-RANGE FORECASTING

Objective predictions. When people wait under a shelter for a downpour to end, they are making a very-short-range weather forecast. They are assuming, based on past experience, that such hard rain usually does not last very long. In short-term predictions the challenge for the forecaster is to improve on what the layperson can do. For years the type of situation represented in the above example proved particularly vexing for forecasters, but since the mid-1980s they have been developing a method called nowcasting to meet precisely this sort of challenge. In this method, radar and satellite observations of local atmospheric conditions are processed and displayed rapidly by computers to project weather several hours in advance. The U.S. National Oceanic and Atmospheric Administration operates a facility known as PROFS (Program for Regional Observing and Forecasting Services) in Boulder, Colo., specially equipped for nowcasting.

Nowcasting

Meteorologists can make somewhat longer-term forecasts (those for six, 12, 24, or even 48 hours) with considerable skill because they are able to measure and predict atmospheric conditions for large areas by computer. Using models that apply their accumulated expert knowledge quickly, accurately, and in a statistically valid form, meteorologists are now capable of making forecasts objectively (see above). As a consequence, the same results are produced time after time from the same data inputs, with all analysis accomplished mathematically. Unlike the prognostications of the past made with subjective methods, objective forecasts are consistent and can be studied, reevaluated, and improved.

Another technique for objective short-range forecasting is called MOS (for Model Output Statistics). Conceived by Harry R. Glahn and D.A. Lowry of the U.S. National Weather Service, this method involves the use of data relating to past weather phenomena and developments to extrapolate the values of certain weather elements, usually for a specific location and time period. It overcomes the weaknesses of numerical models by developing statistical relations between model forecasts and observed weather. These relations are then used to translate the model forecasts directly to specific weather forecasts. For example, a numerical model might not predict the occurrence of surface winds at all, and whatever winds it did predict might always be too strong. MOS relations can automatically correct for errors in wind speed and produce quite accurate forecasts of wind occurrence at a specific point, such as Heathrow Airport near London. As long as numerical weather prediction models are imperfect, there may be many uses for the MOS technique.

Model Output Statistics

Predictive skills and procedures. Short-range weather forecasts generally tend to lose accuracy as forecasters attempt to look farther ahead in time. Predictive skill is greatest for periods of about 12 hours and is still quite substantial for 48-hour predictions (Figure 66). An increasingly important group of short-range forecasts are economically motivated. Their reliability is determined in the marketplace by the economic gains they produce (or the losses they avert).

Weather warnings are a special kind of short-range forecast; the protection of human life is the forecaster's greatest challenge and source of pride. The first national weather forecasting service in the United States (the predecessor of the Weather Bureau) was in fact formed, in 1870, in response to the need for storm warnings on the Great Lakes. Increase Lapham of Milwaukee urged Congress to take action to reduce the loss of hundreds of lives incurred each year by Great Lakes shipping during the 1860s. The effectiveness of the warnings and other forecasts assured the future of the American public weather service.

Weather warnings

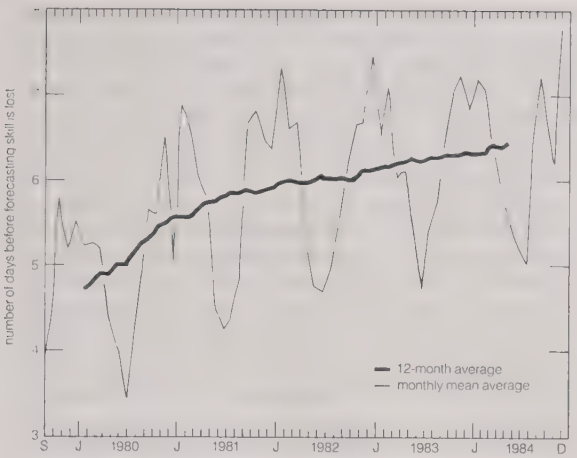

Figure 66: Predictive skill of the European Centre for Medium Range Weather Forecasting (ECMWF) model, September 1979–December 1984, shown in terms of the number of days into the forecast before accuracy is lost.

From L.O. Bengtsson, "Medium-Range Forecasting—The Experience at ECMWF," *Bulletin of the American Meteorological Society* (September 1985)

Weather warnings are issued by government and military organizations throughout the world for all kinds of threatening weather events: tropical storms variously called hurricanes, typhoons, or tropical cyclones, depending on location (see above); great oceanic gales outside the tropics spanning hundreds of kilometres and at times packing winds comparable to those of tropical storms; and, on land, flash floods, high winds, fog, blizzards, ice, and snowstorms.

A particular effort is made to warn of hail, lightning, and wind gusts associated with severe thunderstorms, sometimes called severe local storms (SELS) or simply severe weather. Forecasts and warnings also are made for tornadoes, those intense, rotating windstorms that represent the most violent end of the weather scale (see above). Destruction of property and the risk of injury and death are extremely high in the path of a tornado, especially in the case of the largest systems (sometimes called maxi-tornadoes).

Because tornadoes are so uniquely life-threatening and because they are so common in various regions of the United States, the National Weather Service operates a National Severe Storms Forecasting Center (NSSFC) in Kansas City, Mo., where SELS forecasters survey the atmosphere for the conditions that can spawn tornadoes or severe thunderstorms. This group of SELS forecasters, assembled in 1952, monitors temperature and water vapour in an effort to identify the warm, moist regions where thunderstorms may form and studies maps of pressure and winds to find regions where the storms may organize into mesoscale structures. The group also monitors jet streams and dry air aloft that can combine to distort ordinary thunderstorms into rare rotating ones with tilted chimneys of upward rushing air that, because of the tilt, are unimpeded by heavy falling rain. These high-speed updrafts can quickly transport vast quantities of moisture to the cold upper regions of the storms, thereby promoting the formation of large hailstones. The hail and rain drag down air from aloft to complete a circuit of violent, cooperating updrafts and downdrafts.

By correctly anticipating such conditions, SELS forecasters are able to provide time for the mobilization of special observing networks and personnel. If the storms actually develop, specific warnings are issued based on direct observations. This two-step process consists of the tornado or severe thunderstorm watch, which is the forecast prepared by the SELS forecaster, and the warning, which is usually released by a local observing facility. The watch may be issued when the skies are clear, and it usually covers a number of counties. It alerts the affected area to the threat but does not attempt to pinpoint which communities will be affected.

Severe local storm watch

By contrast, the warning is very specific to a locality and calls for immediate action. Radar of various types can be used to detect the large hailstones, the heavy load of raindrops, the relatively clear region of rapid updraft, and even the rotation in a tornado. These indicators, or an actual sighting, often trigger the tornado warning. In effect, a warning is a specific statement that danger is imminent, whereas a watch is a forecast that warnings may be necessary later in a given region.

LONG-RANGE FORECASTING

Techniques. Extended-range, or long-range, weather forecasting has had a different history and a different approach from short- or medium-range forecasting. In most cases, it has not applied the synoptic method of going forward in time from a specific initial map. Instead, long-range forecasters have tended to use the climatological approach, often concerning themselves with the broad weather picture over a period of time rather than attempting to forecast day-to-day details.

Application of the climatological approach

There is good reason to believe that the limit of day-to-day forecasts based on the "initial map" approach is about two weeks. Most long-range forecasts thus attempt to predict the departures from normal conditions for a given month or season. Such departures are called anomalies. A forecast might state that "spring temperatures in Minneapolis have a 65 percent probability of being above normal." It would likely be based on a forecast anomaly map such as that shown in Figure 67, which shows positive temperature anomalies in the northern United States and negative anomalies to the south. No attempt is made to specify which spring days will be warmer than normal. Moreover, there is no implication that, even if the forecast is correct, no very cold weather will occur that spring. The only implication is that, when the season is over, in two

From (top) Extended Forecast Group, U.S. National Weather Service, National Oceanic and Atmospheric Administration; (bottom) J. Namias, "Remarks on the Potential for Long-Range Forecasting," *Bulletin of the American Meteorological Society* (February 1985)

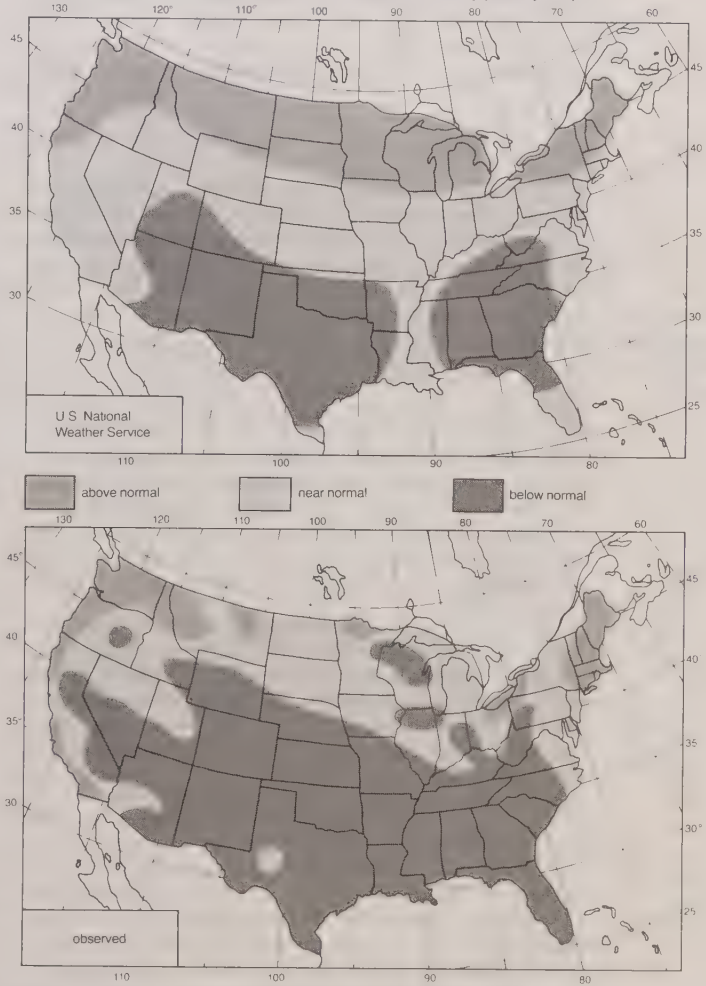

Figure 67: (Top) U.S. National Weather Service forecast and (bottom) observed temperature anomaly pattern for the spring of 1983.

of the three years for which such a forecast is made, the season will have been warmer than usual.

The U.S. Weather Bureau began making experimental long-range forecasts just before the beginning of World War II, and its successor, the National Weather Service, continues to express such predictions in probabilistic terms, making it clear that they are subject to uncertainty. Verification shows that forecasts of temperature anomalies are more reliable than those of precipitation, that monthly forecasts are better than seasonal ones, and that winter months are predicted somewhat more accurately than other seasons.

Extensive use of the analog method

Prior to the 1980s the technique commonly used in long-range forecasting relied heavily on the analog method, in which groups of weather situations (maps) from previous years were compared to those of the current year to determine similarities with the atmosphere's present patterns (or "habits"). An association was then made between what had happened subsequently in those "similar" years and what was going to happen in the current year. Most of the techniques were quite subjective, and there were often disagreements of interpretation and consequently uneven quality and marginal reliability.

Persistence (warm summers follow warm springs) or anti-persistence (cold springs follow warm winters) also were used, even though, strictly speaking, most forecasters consider persistence forecasts "no-skill" forecasts. Yet, they too have had limited success.

Prospects for new procedures. In the last quarter of the 20th century the approach of and prospects for long-range weather forecasting have changed significantly. Stimulated by the work of Jerome Namias, who headed the U.S. Weather Bureau's Long-Range Forecast Division for 30 years, scientists began to look at ocean-surface temperature anomalies as a potential cause for the temperature anomalies of the atmosphere in succeeding seasons and at distant locations. At the same time, other American meteorologists, most notably John M. Wallace, showed how certain repetitive patterns of atmospheric flow were related to each other in different parts of the world. With satellite-based observations available, investigators began to study the El Niño phenomenon (see above *El Niño/Southern Oscillation*). Atmospheric scientists also revived the work of Gilbert Walker, an early 20th-century British climatologist who had studied the Southern Oscillation, the aforementioned up-and-down fluctuation of atmospheric pressure in the Southern Hemisphere. Walker had investigated related air circulations (later called the Walker Circulation) that resulted from abnormally high pressures in Australia and low pressures in Argentina or vice versa.

All of this led to new knowledge about how the occurrence of abnormally warm or cold ocean waters and of abnormally high or low atmospheric pressures could be interrelated in vast global connections. Knowledge about these links—El Niño/Southern Oscillation (ENSO)—and about the behaviour of parts of these vast systems enables forecasters to make better long-range predictions, at least in part, because the ENSO features change slowly and somewhat regularly. This approach of studying interconnections between the atmosphere and the ocean may represent the beginning of a revolutionary stage in long-range forecasting.

Since the mid-1980s, interest has grown in applying numerical weather prediction models to long-range forecasting. In this case, the concern is not with the details of weather predicted 20 or 30 days in advance but rather with objectively predicted anomalies. The reliability of long-range forecasts, like that of short- and medium-range projections, has improved substantially in recent years. Yet, many significant problems remain unsolved, posing interesting challenges for all those engaged in the field.

(J.J.Ca.)

SCIENTIFIC WEATHER MODIFICATION

General considerations

Humans have long sought to purposefully alter such atmospheric phenomena as clouds, rain, snow, hail, lightning, thunderstorms, tornadoes, hurricanes, and cyclones. The modern era of scientific weather modification began in 1946 with work by Vincent J. Schaefer and Irving Langmuir at the General Electric Research Laboratories in Schenectady, N.Y. Schaefer discovered that when Dry Ice pellets were dropped into a cloud composed of water droplets in a deep-freeze box, the droplets rapidly were replaced by ice crystals, which increased in size and then fell to the bottom of the box.

Schaefer–Langmuir experiments

The Schaefer–Langmuir experiments in the laboratory and the atmosphere demonstrated that so-called supercooled clouds—namely those composed of water droplets at temperatures below freezing—could be dissipated. When the supercooled clouds were seeded with grains of Dry Ice, ice crystals formed and grew large enough to fall out of the clouds.

Certain substances other than Dry Ice can be used to seed clouds. For example, when silver iodide and lead iodide are burned, they create a smoke of tiny particles. These particles produce ice crystals in supercooled clouds below temperatures of about −5° C. Although many other materials can cause ice crystals to form, the above-mentioned are the most widely used. For the most part, Dry Ice is dispersed from airplanes, but silver iodide nuclei may be generated on the ground and carried upward by air currents, introduced from airplanes, or produced by pyrotechnic devices such as rockets or exploding artillery shells.

A wide variety of scientific tests and operational weather modification projects have been performed in many countries. The largest programs have been in the United States, the former Soviet Union, Australia, and France.

Most weather modification programs in the United States have dealt with rain or snow. Although there is still considerable debate about the effectiveness of cloud seeding, the evidence indicates that under certain meteorological conditions, ice nuclei seeding may increase precipitation by amounts ranging up to some tens of percent. In other circumstances decreases may occur, and, in still others, seeding has no effect.

In Russia and various other former Soviet republics the major programs of weather modification were aimed at reducing the fall of damaging hail. Experimentation in this area was apparently successful. Procedures involved introducing ice nuclei into potential hail clouds by means of artillery or rockets. Attempts to modify hailstorms in other countries have had mixed success.

A number of hurricanes have been seeded with ice nuclei by American scientists. Although results have been inconclusive, some meteorologists believe it is possible to reduce hurricane intensities in some instances. Before asserting that hurricanes can be beneficially modified, however, more research is needed. Limited attempts to modify mid-latitude cyclones in the past have not been successful. In the case of tornadoes, knowledge of their dynamic structure remains limited, and no attempts have been made to control them.

The effective extent of weather modification

There are many misunderstandings about the present status of weather modification. Present techniques are concerned mostly with the influence of existing cloud systems. There is no evidence and no reason for believing, at this stage, that cloud seeding may cause or end droughts. Such dry periods result from peculiarities in the general circulation of the atmosphere that lead to sinking air and cloud-free skies in areas accustomed to precipitation. When there are no clouds present, there can be no cloud seeding.

As meteorologists have developed schemes for changing the weather, the ecological, social, and legal problems have become more serious. Many U.S. states have laws governing weather modification activities. Lawsuits have been filed in which the parties have contested ownership of the clouds and the precipitation therein.

Methods of modifying atmospheric phenomena

CLOUD SEEDING

As previously discussed, clouds form when atmospheric moisture condenses on small particles in the atmosphere called condensation nuclei. Typically, a cloud is composed of tiny spheres of water that range in diameter from a few micrometres to a few tens of micrometres. The number of cloud droplets per cubic centimetre ranges from less than 100 to more than 1,000; 200 droplets per cubic centimetre is approximately an average value.

An important characteristic of a cloud is its temperature. When it is everywhere above 0° C, the cloud is said to be warm. Often, clouds develop at altitudes where temperatures are below 0° C, but the droplets do not freeze because of the purity of the water. Such clouds are said to be supercooled. In the atmosphere, supercooling to temperatures of −10° C or even −20° C is not unusual. The lower the temperature, the greater the likelihood that the droplets will intercept so-called ice nuclei, which cause them to freeze. At temperatures below about −40° C, virtually all clouds are composed of ice crystals.

Many all-liquid clouds, whether warm or supercooled, are stable in the sense that the droplets are limited in size to a few tens of micrometres, and the clouds may last for some time without yielding rain or snow.

Sometimes nature is deficient in ice nuclei, and as a result supercooled clouds may persist for many hours. When this is the case, the addition of ice nuclei can upset the cloud stability by causing ice crystals to form; these can then grow and result in precipitation.

Substances used in cloud seeding

The introduction of any substance into clouds for the purpose of changing them is called cloud seeding. Warm clouds (above 0° C) have been seeded with materials such as sodium chloride or calcium chloride particles or by a water spray. The objective of these procedures is to produce giant cloud droplets that will grow by coalescence, fall, and sweep out smaller cloud droplets. Fogs over airports have been seeded in order to reduce the density of the cloud and to improve the visibility and ceiling conditions. Warm convective clouds have been seeded in an effort to increase rainfall.

Aircraft have been used to dispense a water spray or salt particles. In some cases, salt-water sprays have been dispersed. Unfortunately, such solutions tend to be corrosive to aircraft surfaces and have to be handled carefully. In some programs sodium chloride particles in powdered form have been blown up from the ground.

Most cloud-modification activities have been concerned with supercooled clouds and have involved seeding with ice nuclei. As noted above, the first substance found to be effective as a cloud-seeding agent was Dry Ice. Its temperature is so low (about −78° C) that it causes ice crystals to form spontaneously from water vapour. It has been estimated that a gram of Dry Ice will produce at least 3×10^{10} ice crystals. The most common procedure for seeding with Dry Ice is to fly over a cloud and disperse crushed pellets, less than a millimetre to a few millimetres in diameter, along the path of flight. A typical seeding rate might be several kilograms of Dry Ice per kilometre of flight.

Dry Ice is no longer widely employed as a cloud-seeding agent because it suffers from the disadvantage of having to be delivered to the supercooled regions of the cloud and from the fact that, once a pellet of Dry Ice has evaporated, it can no longer affect the cloud. Supercooled clouds are now most commonly seeded with tiny particles of silver iodide.

Seeding with silver iodide

There are many techniques for seeding with silver iodide. All of them produce large numbers of minute particles that range in diameter from about 0.01 to 0.1 micrometre. A common procedure is to dissolve silver iodide in a solution of sodium iodide in acetone. The concentration of silver iodide may range from 1 to 10 percent. When the solution is burned in a well-ventilated chamber at a temperature of about 1,100° C, a very large number of ice nuclei are produced. The concentration increases rapidly as the temperature decreases. A typical quantity at −10° C is 10^{13} ice nuclei per gram of silver iodide. Exposure to ultraviolet light causes rapid deactivation of the silver iodide nuclei. The concentrations of nuclei may decrease by perhaps a factor of 10 for each hour of exposure.

In the United States, France, Switzerland, and Argentina, a great deal of the silver iodide seeding has been done by means of ground generators. When this is the case, air currents are expected to transport the nuclei into the supercooled parts of the cloud.

Experimenters in the United States, Australia, Israel, and other countries have used airplanes for dispersing silver iodide particles. For the most part, silver iodide in acetone has been burned in generators suspended from the wings of one or more airplanes. In some tests pyrotechnical devices have been employed for this purpose. When they are dropped from above into clouds, a solid mixture of silver iodide and an inflammable substance is ignited.

Soviet experimenters relied on rockets fired from the ground. This procedure was first employed in Italy, but the Soviets refined it by employing a superior rocket in which the pyrotechnic mixture could be ignited anywhere along the path of flight. Also in the Soviet experiments a great deal of ice-nuclei seeding was done by means of 70-millimetre artillery guns that fired projectiles containing 100 to 200 grams of lead iodide or silver iodide. At a predetermined position the projectile exploded and dispersed the ice nuclei.

Other cloud-modification methods

Various other schemes for seeding clouds have been employed. One that is used at Orly Airport in France involves tanks of propane (see below). When propane gas is released, it expands and cools the air, and, as a result, ice crystals are produced. Some tests have been made of this procedure in the United States.

Most cloud-modification work has been concerned with changing the size of cloud particles or the buoyancy of the cloud air. A number of scientists have been interested in developing procedures for changing the electrical structure of clouds. One practical goal has been the reduction of the number of forest fires caused by lightning. Small clouds have been modified electrically by releasing large quantities of ions from a long piece of wire mounted near the ground.

Attempts to change the electrical nature of large thunderstorms have involved seeding with ice nuclei and, in another set of experiments, with large numbers of short metal strips. The object has been to prevent the electrical charge of clouds from becoming so concentrated that a lightning stroke would occur.

FOG DISSIPATION

In order for aircraft to take off and land, it is necessary that the ceiling (the height of the cloud base above the ground) and visibility be above certain minimum values. It has been estimated that, in the United States alone, airport shutdowns by fog were costing the airlines many millions of dollars annually. The vital effect of low ceilings and visibilities on military aircraft operation was forcefully emphasized during World War II when Allied aircraft flew out of foggy England.

During the late 1930s attempts were made to dissipate fogs by seeding them with salt particles, in particular calcium chloride. Some success was experienced, but this technique did not appear to be practical. During the mid-1940s large quantities of heat were used to clear airport runways. The scheme called FIDO (Fog Investigation Dispersal Operations) employed kerosene burners along the runways. The heat they released decreased the relative humidity of the air and caused droplet evaporation and a sufficient improvement in ceiling and visibility to allow aircraft to land or take off.

The dissipation of supercooled fogs by means of ice nuclei has been going on for many years. Tables have been prepared that specify the quantities of Dry Ice to be dispersed, depending on such factors as wind speed, cloud thickness, and temperature. A typical seeding rate might be about two kilograms per kilometre of flight. Special equipment has been developed for the purpose of dispensing Dry Ice flakes or pellets from an airplane or from the ground.

A network of propane gas sprayers and associated tanks of liquid propane are installed around the periphery of

Orly Airport. The particular sprayers to be activated on any foggy occasion are determined automatically by a computer that is fed meteorological data on visibility, temperature, and wind velocity.

Investigations have been made of the value of acoustical techniques for clearing fogs. Such schemes work well in a cloud chamber where standing sound waves can be set up, but there is no evidence that reasonable sound sources can effectively change the characteristics of fogs in the free atmosphere.

PRECIPITATION MODIFICATION

Shortly after Schaefer's proof that Dry Ice seeding could modify supercooled stratus clouds, there were many projects aimed at increasing rain or snow by economically important amounts. The first cloud-seeding tests demonstrated that, in the course of dissipating stratiform clouds, some small amounts of snow fell that would not have fallen had there been no seeding. Certain meteorologists hypothesized that by seeding thick clouds it should be possible to cause substantial increases of rain or snow. Unfortunately, from the point of view of designing a scientific experiment that would put this hypothesis to the test, the thicker the cloud, the better the chance of natural precipitation. Cloud thickness alone does not allow a unique specification of the quantity of rain or snow. Other factors such as the strength and persistence of the cloud updraft, cloud-top temperature, the horizontal dimensions of the cloud, and its microphysical properties influence the amount of precipitation.

Problems of analyzing results

The complex nature of clouds has so far thwarted attempts to develop quantitative forecasts of rainfall of sufficient accuracy to be used to evaluate a cloud-seeding scheme. Also, as is well known, precipitation is highly variable in space and time. As a result, it is not possible, on the basis of a physical theory, to answer satisfactorily the question, "How much rain or snow would have fallen if there had been no cloud seeding?"

The most reliable evidence concerning the effects of cloud seeding has come from programs in which statistical techniques were employed to design experiments and test hypotheses dealing with the effectiveness of any particular cloud-seeding scheme. Many experimental designs and evaluating procedures have been used since the late 1940s. There have been many disagreements among scientists and statisticians about the interpretation of programs that have been conducted in the past.

A question of fundamental importance has been raised about the scientific value of precipitation-augmentation projects conducted by private or commercial interests. Such operations usually have been based on the assumption that seeding would increase precipitation. They have not been conducted as experiments designed to test whether or not such would be the result. Certain prominent statisticians have taken the position that because these projects have not purposefully incorporated "randomized" or other control procedures to reduce the effects of bias by the operators, the data they have yielded cannot be used to test the efficacy of cloud seeding. On these grounds, in 1957 optimistic conclusions by the U.S. Advisory Committee on Weather Control on the effectiveness of cloud seeding were rejected by various statisticians. The final report of the committee concluded that precipitation from winter supercooled clouds over the mountainous western United States was increased by some 10 to 15 percent as a result of silver iodide seeding. In 1966 a special panel of the National Academy of Sciences, again employing data mostly derived from private or commercial operators, arrived at almost the same conclusion.

The most recent evidence indicates that sometimes ice-nuclei seeding may increase precipitation from certain supercooled clouds by some tens of percent. In other circumstances the seeding may lead to decreases of about the same magnitude. In still other meteorological situations seeding is ineffective. With a few exceptions it still is not possible to specify the conditions under which positive or negative effects would be expected to occur. It appears that in certain types of supercooled clouds the temperature at the upper boundary of the cloud is an important but not sole indicator of the most likely effects of ice-nuclei seeding.

Use of mathematical models of clouds and cloud systems

Since the late 1960s, increasing effort has been made to develop mathematical models of clouds and cloud systems. Once an accurate model exists, it is possible to calculate the expected results of ice-nuclei seeding by means of a computer. This approach was employed by Joanne Simpson of the Environmental Science Services Administration and others to test the effects of heavy doses of silver iodide on cumulonimbus clouds. She found that the effects of ice nuclei on large convective clouds conformed closely with theoretical predictions. Certain specified clouds were caused to grow and to produce more rain than they would have if they had not been seeded (Figure 68).

An important but still unresolved question deals with effects of cloud seeding on precipitation downwind from the target area. For the most part studies have shown excesses of precipitation, but there still exists the possibility of decreases not only far downwind but in all other directions as well.

A number of tests have been made to stimulate rainfall from warm cumulus clouds by seeding them with sodium chloride particles. Experiments in India and certain other countries were reported to have increased the amount of rainfall successfully.

MODIFICATION OF OTHER WEATHER PHENOMENA

Electricity in clouds. Various schemes have been employed to modify the electrical nature of clouds and the occurrence of cloud-to-ground lightning. Research has shown that by releasing large quantities of ions near the ground, it is possible to influence the electric properties of small cumulus clouds. This does not mean, however, that large clouds could be influenced in this manner.

There is no convincing evidence supporting the assertion that the release of electrically charged particles will influence the precipitation from fogs or clouds.

An extensive program dealing with the modification of lightning storms has been conducted by the U.S. Forest Service. Potential lightning storms were seeded heavily with silver iodide nuclei. The lightning characteristics of some traveling thunderstorms apparently were changed, but it still was not demonstrated conclusively that cloud-to-ground lightning can be reduced.

Hail suppression. In many areas of the world hail does enormous destruction to agriculture, particularly fruit orchards and grain fields. There have been cloud-seeding projects aimed at reducing hail damage. Some operations have attempted to put so many nuclei into the supercooled parts of cumulonimbus that they would be almost totally converted to ice crystals. Such a procedure, called overseeding, is not considered practical because of the large quantities of material needed to seed the clouds over an area great enough to have an appreciable effect.

Most hail-suppression attempts have been based on the

Reducing the size of hailstones

concept that damage will be reduced if the hailstone sizes are reduced. This does not require overseeding. Consider, for example, an unseeded cloud that produces one hailstone having a two-centimetre diameter in each cubic metre of air. If ice-nuclei seeding could cause 100 uniform hailstones in the same volume from the same available quantity of supercooled water, their diameters would be about 0.4 centimetre. The small stones would melt as they fell through the layer of warm air below the freezing level. Even if they did not melt completely to form rain, by the time the hailstones reached the ground they would be too small to do any serious damage.

Silver iodide seeding of potential hailstorms has been carried out in many countries. Most of the ice nuclei have been dispersed from ground-based or aircraft-mounted generators. In Switzerland it appeared that there may have been more hail produced by seeding. In Argentina the results seemed to depend on the type of weather situation. In the United States varying results have been reported.

Soviet experimenters injected ice nuclei directly into the supercooled parts of clouds by means of rockets or artillery. In the latter technique a projectile explodes and disperses the nuclei. The rockets carry a cylinder of a pyrotechnic substance impregnated with silver iodide or lead iodide. It passes through the cloud while burning for a period of 45 seconds. Spectacular success in hail reduction was reported by Soviet scientists. The benefit-to-cost ratios cited ranged from 4 to 1 up to 17 to 1. There have been no independent tests of these procedures, and as a result many other atmospheric scientists have hesitated to accept the claims of success at face value.

Severe storms. Hurricanes can cause widespread destruction and human misery. An average hurricane has tremendous energy. In one day the energy released is about 1.6×10^{13} kilowatt-hours, or at least 8,000 times more than the electrical power generated each day in the United States. This quantity is equivalent to a daily explosion of 500,000 atomic bombs of the 20-kiloton Nagasaki variety. These numbers should make it clear that it would be impractical to attempt to modify hurricanes by a brute force approach. It is necessary to find a means whereby a small input of energy may upset a natural instability and lead to large results. Ice-nuclei seeding is the one such approach now under investigation.

Hurricane-seeding experiment

The first hurricane-seeding test was carried out in 1947 by Irving Langmuir and his colleagues, who distributed about 91 kilograms of crushed Dry Ice in a storm. They apparently were convinced that the seeding caused a change in the track followed by the storm.

On Aug. 18 and 20, 1969, Hurricane Debbie was seeded as a part of Project Stormfury, a series of hurricane-modification experiments conducted by the Environmental Science Services Administration and the U.S. Navy. Heavy doses of silver iodide were dropped into the hurricane clouds from airplanes. The maximum measured wind speeds in the hurricane decreased by 31 and 15 percent on the two seeded days. On August 19, the day between the two flights, the storm reportedly reintensified.

The results of this experiment were in the direction predicted by a mathematical model of a hypothetical hurricane. Because the measured winds in two hurricanes seeded in earlier years also decreased, Project Stormfury scientists were optimistic that hurricanes could be modified beneficially, but many more experiments are needed before attempting the seeding of hurricanes close to land.

The violent nature of tornadoes would appear to dictate substantial programs of research to increase our understanding and control of these storms. In fact, very little scientific attention has been devoted to attempts to modify tornadoes. It has been speculated that they might be influenced by firing rockets into them and distributing materials to modify their temperature structure or electrical properties. Unfortunately, so little is known about the tornadoes that few scientists have confidence that such schemes would be effective.

CHANGES IN THE RADIATION BALANCE NEAR THE GROUND

When air moves against a mountain slope, it is forced to rise, and as a result clouds and precipitation often are produced. Air moving over heated islands in the tropical oceans acts in a similar fashion even when the terrain is flat. The ground and the air over it warm up more than does the adjacent water. A rising convection current develops over the island. The result is that air moving over the island rises in a manner similar to that over a mountain. This is known as the "thermal mountain effect."

Scientists of the Esso Research and Engineering Company proposed that by covering large areas with asphalt it might be possible, over land, to simulate the results observed over tropical islands. The black asphalt would become hotter than surrounding lighter soil. It has been speculated that this would lead to convective currents, a thermal mountain, and more precipitation.

It has been proposed that cloud seeding be used to open large holes (about 100 kilometres in diameter) in supercooled layer clouds in order to change the radiation balance of a region. Clouds reflect perhaps 70 percent of the Sun's rays, while the ground reflects about 20 percent. If a deck of supercooled cloud could be dissipated during the daytime, there would be more solar energy absorbed, local warming, and possibly changes in atmospheric motions and behaviour. If large areas of clouds were dissipated at night, there would be excessive outgoing radiation and cooling. The effects of the resultant temperature drop over a large area still have not been evaluated thoroughly.

Atmospheric humidity and precipitation: Discussions of water vapour in the atmosphere and global water budgets are found in NEIL WELLS, *The Atmosphere and Ocean: A Physical Introduction* (1986); and F.H. LUDLAM, *Clouds and Storms: The Behavior and Effect of Water in the Atmosphere* (1980). Forms of precipitation are surveyed in B.J. MASON, *Clouds, Rain and Rainmaking,* 2nd ed. (1975); W.E. KNOWLES MIDDLETON, *A History of the Theories of Rain and Other Forms of Precipitation* (1965); and D.M. GRAY and D.H. MALE (eds.), *Handbook of Snow: Principles, Processes, Management & Use* (1981). B.J. MASON, *The Physics of Clouds,* 2nd ed. (1971), is an authoritative text. See also the cloud atlas by RICHARD SCORER, *Clouds of the World: A Complete Color Encyclopedia* (1972). (Ed.)

Atmospheric pressure and wind: General textbooks with effective discussions of wind and pressure are FREDERICK K. LUTGENS and EDWARD J. TARBUCK, *The Atmosphere: An Introduction to Meteorology,* 3rd ed. (1986); C. DONALD AHRENS, *Meteorology Today: An Introduction to Weather, Climate, and the Environment,* 2nd ed. (1985); LOUIS J. BATTAN, *Fundamentals of Meteorology,* 2nd ed. (1984); and STANLEY DAVID

GEDZELMAN, *The Science and Wonders of the Atmosphere* (1980). More sophisticated treatment of the wind/pressure relationship is provided by JOHN A. DUTTON, *The Ceaseless Wind: An Introduction to the Theory of Atmospheric Motion*, enl. ed. (1986); JAMES R. HOLTON, *An Introduction to Dynamic Meteorology*, 2nd ed. (1979); JOHN M. WALLACE and PETER V. HOBBS, *Atmospheric Science: An Introductory Survey* (1977); HORACE R. BYERS, *General Meteorology*, 4th ed. (1974); and E. PALMÉN and C.W. NEWTON, *Atmospheric Circulation Systems: Their Structure and Physical Interpretation* (1969). (P.J.S.)

Major forms of weather disturbances: JOE R. EAGLEMAN, *Severe and Unusual Weather* (1983), presents an overview of storms. Types of storms, their attendant phenomena, and their effects are treated in EDWIN KESSLER (ed.), *Thunderstorms—A Social, Scientific, & Technological Documentary*, 3 vol. (1981–82), including studies of tornadoes; R.H. GOLDE (ed.), *Lightning*, 2 vol. (1977); MARTIN A. UMAN, *Lightning* (1969, reissued 1984), a fundamental work; NARAYAN R. GOKHALE, *Hailstorms and Hailstone Growth* (1975); RICHARD A. ANTHES, *Tropical Cyclones: Their Evolution, Structure and Effects* (1982); ROBERT H. SIMPSON and HERBERT RIEHL, *The Hurricane and Its Impact* (1981); and SNOWDEN D. FLORA, *Tornadoes of the United States*, 2nd ed. (1954), a standard work. (L.J.B./N.R.W./Ed.)

Climatic variations and changes: Overviews are given by M.I. BUDYKO, *The Earth's Climate, Past and Future* (1982; originally published in Russian, 1980), a masterly account by the founder of contemporary climatology; H.H. LAMB, *Climate, History, and the Modern World* (1982); T.M.L. WIGLEY, M.J. INGRAM, and G. FARMER, *Climate and History: Studies in Past Climates and Their Impact on Man* (1981); and MICHAEL R. RAMPINO *et al., Climate, History, Periodicity, and Predictability* (1987), on the relationship between climate cycles and their causes, with an extensive bibliography. A.B. PITTOCK *et al.* (eds.), *Climatic Change and Variability: A Southern Perspective* (1978), offers an excellent antipodean analysis. EMMANUEL LE ROY LADURIE, *Times of Feast, Times of Famine: A History of Climate Since the Year 1000* (1971, reissued 1988; originally published in French, 1967), is an interdisciplinary study using many data sources to document climatic variations. R.S. BRADLEY, *Quaternary Paleoclimatology: Methods of Paleoclimatic Reconstruction* (1985), summarizes research techniques. (F.K.H.)

Climatic classification: Useful introductory discussions can be found in ARTHUR N. STRAHLER and ALAN H. STRAHLER, *Modern Physical Geography*, 3rd ed. (1987); and HERMANN FLOHN, *Climate and Weather* (1969; originally published in German, 1968). More advanced treatment is provided by A. HENDERSON-SELLERS and P.J. ROBINSON, *Contemporary Climatology* (1986); JOHN G. LOCKWOOD, *World Climatic Systems* (1985); ROGER G. BARRY and RICHARD J. CHORLEY, *Atmosphere, Weather, and Climate*, 4th ed. (1982); B.W. ATKINSON, *Dynamical Meteorology: An Introductory Selection* (1981); and R.G. BARRY and A.H. PERRY, *Synoptic Climatology: Methods and Applications* (1973). Specific treatment of the topic is given by JOHN E. OLIVER and L. WILSON, "Climatic Classification," in JOHN E. OLIVER and RHODES W. FAIRBRIDGE (eds.), *The Encyclopedia of Climatology* (1987), pp. 221–237; and JOHN E. OLIVER, *Climate and Man's Environment: An Introduction to Applied Climatology* (1973). The global distribution of major climate types is the subject of GLENN T. TREWARTHA and LYLE H. HORN, *An Introduction to Climate*, 5th ed. (1980); JOHN F. GRIFFITHS and DENNIS M. DRISCOLL, *Survey of Climatology* (1982); HOWARD J. CRITCHFIELD, *General Climatology*, 4th ed. (1983); JOHN G. LOCKWOOD, *World Climatology: An Environmental Approach* (1974); S. NIEUWOLT, *Tropical Climatology: An Introduction to the Climates of the Low Latitudes* (1977); and HERBERT RIEHL, *Climate and Weather in the Tropics* (1979). Particular regions are examined in H.E. LANDSBERG (ed.), *World Survey of Climatology* (1969–)—15 vol. have appeared to 1987; and GLENN T. TREWARTHA, *The Earth's Problem Climates*, 2nd ed. (1981). Climatic data are covered in HOWARD J. CRITCHFIELD, "Climatic Data, Sources of," in OLIVER and FAIRBRIDGE (*op. cit.*), pp. 272–276. Discussion of meso- and microclimates are found in T.R. OKE, *Boundary Layer Climates* (1978); RUDOLF GEIGER, *The Climate near the Ground* (1965; originally published in German, 1961); MASATOSHI M. YOSHINO, *Climate in a Small Area: An Introduction to Local Meteorology* (1975); and HELMUT E. LANDSBERG, *The Urban Climate* (1981). (A.J.A.)

Climate and life: Comprehensive introductions include STEPHEN H. SCHNEIDER and RANDI LONDER, *The Coevolution of Climate and Life* (1984); and JAMES LOVELOCK, *The Ages of Gaia: A Biography of Our Living Earth* (1988), a restatement of a controversial view of interactions between the living and inorganic parts of Earth. Causes of climatic change are explained in detail in B. BOLIN and R.B. COOK (ed.), *The Major Biogeochemical Cycles and Their Interactions* (1983); B. BOLIN *et al., The Greenhouse Effect, Climatic Change, and Ecosystems* (1986); NORMAN MYERS, *Conversion of Tropical Moist Forests* (1980), a clearly argued but controversial account; and ROBERT E. DICKINSON (ed.), *The Geophysiology of Amazonia: Vegetation and Climate Interactions* (1987). The impact of climate on human life is treated in MICHAEL GLANTZ, RICHARD KATZ, and MARIA KRENZ (eds.), *The Societal Impacts Associated with the 1982–83 Worldwide Climate Anomalies* (1987), a report on the effects of the 1982–83 El Niño/Southern Oscillation, published by the National Center for Atmospheric Research; WILFRID BACH, JÜRGEN PANKRATH, and STEPHEN H. SCHNEIDER (eds.), *Food–Climate Interactions* (1981); ROBERT W. KATES, JESSE H. AUSUBEL, and MIMI BERBERIAN, *Climate Impact Assessment: Studies of the Interaction of Climate and Society* (1985); and WILLIAM W. KELLOGG and ROBERT SCHWARE, *Climate Change and Society: Consequences of Increasing Atmospheric Carbon Dioxide* (1981). The impact of human activities on the climate is presented in WILLIAM C. CLARK and R.E. MUNN (eds.), *Sustainable Development of the Biosphere* (1986); MICHAEL C. MACCRACKEN and FREDERICK M. LUTHER (eds.), *Projecting the Climatic Effects of Increasing Carbon Dioxide* (1985); NATIONAL RESEARCH COUNCIL (U.S.), CARBON DIOXIDE ASSESSMENT COMMITTEE, *Changing Climate* (1983); and P.S. LISS and A.J. CRANE, *Man-Made Carbon Dioxide and Climatic Change: A Review of Scientific Problems* (1983). Climate model predictions are explored in STEPHEN H. SCHNEIDER, "Climate Modeling," *Scientific American*, 256(5):72–80 (May 1987); and A. BERGER *et al., Milankovitch and Climate: Understanding the Response to Astronomical Forcing*, 2 vol. (1984). (S.H.S./A.B.Ri.)

Meteorological measurement and weather forecasting: RICHARD A. ANTHES *et al., The Atmosphere*, 3rd ed. (1981), contains general discussions. The history of weather forecasting is recounted in GISELA KUTZBACH, *The Thermal Theory of Cyclones: A History of Meteorological Thought in the Nineteenth Century* (1979); A. KH. KHRGIAN, *Meteorology: A Historical Survey*, 2nd ed. rev. (1970; originally published in Russian, 2nd ed. rev., 1959); PATRICK HUGHES, "American Weather Services," *Weatherwise*, 33(3):100–111 (June 1980); and FREDERICK G. SHUMAN, "Numerical Weather Prediction," *Bulletin of the American Meteorological Society*, 59(1):5–17 (January 1978). Instruments used in weather analysis are examined in the classic texts by W.E. KNOWLES MIDDLETON and ATHELSTAN F. SPILHAUS, *Meteorological Instruments*, 3rd ed. rev. (1953, reprinted 1960); and W.E. KNOWLES MIDDLETON, *History of the Barometer* (1964), *A History of the Thermometer and Its Uses in Meteorology* (1966), and *Invention of the Meteorological Instruments* (1969); as well as in LEO J. FRITSCHEN and LLOYD W. GAY, *Environmental Instrumentation* (1979), with coverage limited to measurements at the Earth's surface; STUART G. BIGLER, "Radar: A Short History," *Weatherwise*, 34(4):158–163 (August 1981); LOUIS J. BATTAN, *Radar Observation of the Atmosphere*, rev. ed. (1973); R.S. SCORER, *Cloud Investigation by Satellite* (1986); VINCENT J. OLIVER, "A Primer: Using Satellites to Study the Weather," *Weatherwise*, 34(4):164–170 (August 1981); ERIC C. BARRETT and DAVID W. MARTIN, *The Use of Satellite Data in Rainfall Monitoring* (1981); and ERIC C. BARRETT, *Climatology from Satellites* (1974). A good overview of forecasting is found in LANCE F. BOSART, "Weather Forecasting," ch. 4 in DAVID D. HOUGHTON (ed.), *Handbook of Applied Meteorology* (1985), pp. 205–279. Methods and problems of forecasting are presented in JAROMIR NEMEC, *Hydrological Forecasting: Design and Operation of Hydrological Forecasting Systems* (1986); D.M. BURRIDGE and E. KÄLLÉN (eds.), *Problems and Prospects in Long and Medium Range Weather Forecasting* (1984); K.A. BROWNING (ed.), *Nowcasting* (1982); and three articles from *Bulletin of the American Meteorological Society:* DONALD L. GILMAN, "Long-Range Forecasting: The Present and the Future," 66(2):159–164 (February 1985); JEROME NAMIAS, "Remarks on the Potential for Long-Range Forecasting," 66(2):165–173 (February 1985); and L. BENGTSSON, "Medium-Range Forecasting—The Experience at ECMWF," 66(9):1133–46 (September 1985). (J.J.Ca.)

Scientific weather modification: NATIONAL RESEARCH COUNCIL (U.S.) COMMITTEE ON ATMOSPHERIC SCIENCES, *Weather and Climate Modification: Problems and Prospects*, 2 vol. (1966), an authoritative survey, supplemented by *Weather and Climate Modification: Problems and Progress* (1973); GEORG BREUER, *Weather Modification: Prospects and Problems* (1979; originally published in German, 1976), a nontechnical examination of the subject; W.R.D. KNIGHT (eds.), *Hail: A Review of Hail Science and Hail Suppression* (1977); ARNETT S. DENNIS, *Weather Modification by Cloud Seeding* (1980); and W.N. HESS (ed.), *Weather and Climate Modification* (1974), a comprehensive account of all aspects of weather modification. Appropriate articles can be found in *The Journal of Weather Modification* (annual). (L.J.B./Ed.)

Cnidarians

The phylum Cnidaria (cnidarians) comprises a diverse group of aquatic animals. The phylum is made up of four classes: Hydrozoa (hydrozoans); Scyphozoa (scyphozoans); Anthozoa (anthozoans); and Cubozoa (cubozoans). The nearly 9,000 species share several attributes, supporting the theory that they had a single origin. Variety and symmetry of body forms, varied coloration, and the sometimes complex life histories of cnidarians fascinate layperson and scientist alike. Inhabiting all marine and some freshwater environments, these animals are most abundant and diverse in tropical waters. Their calcareous skeletons form the frameworks of the reefs and atolls in most tropical seas, including the Great Barrier Reef that extends more than 2,000 kilometres along the northeastern coast of Australia.

Only cnidarians manufacture microscopic intracellular stinging capsules, known as nematocysts or cnidae, which give the phylum its name. An alternative name for the phylum is Coelenterata, which refers to their simple organization around a central body cavity (the coelenteron). As first defined, Coelenterata included not only the animals now designated cnidarians but also sponges (phylum Porifera) and comb jellies (phylum Ctenophora). In contemporary usage, "coelenterate" generally refers only to cnidarians, but the latter term is used in order to avoid ambiguity.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* especially section 313.

This article is divided into the following sections:

GENERAL FEATURES

Size range and diversity of structure. Cnidarians are considered primitive because they are radially symmetrical (*i.e.,* similar parts are arranged symmetrically around a central axis), they lack cephalization (concentration of sensory organs in a head), their bodies have two cell layers rather than the three of so-called higher animals, and the saclike coelenteron has one opening (the mouth). They are the most primitive of animals whose cells are organized into distinct tissues, but they lack organs. Cnidarians have two body forms—polyp and medusa (Figures 1 and 2).

Medusae and polyps

The body of a medusa, commonly called a jellyfish, usually has the shape of a bell or an umbrella, with tentacles hanging downward at the margin. The tubelike manubrium hangs from the centre of the bell, connecting the mouth at the lower end of the manubrium to the coelenteron within the bell. Most medusae are slow-swimming, planktonic animals. In a polyp, the mouth and surrounding tentacles face upward, and the cylindrical body is generally attached by its opposite end to a firm substratum. The mouth is at the end of a manubrium in many hydrozoan polyps. Anthozoan polyps have an internal pharynx, or stomodaeum, connecting the mouth to the coelenteron.

Most species of cubozoans, hydrozoans, and scyphozoans alternate in their life cycles between medusoid and polypoid body forms, with medusae giving rise sexually to larvae that metamorphose into polyps, while polyps produce medusae asexually. Anthozoans are polypoid cnidarians and do not have a medusa stage. Commonly polyps, and in some species medusae too, can produce more of their own kind asexually.

One body form may be more conspicuous than the other. For example, scyphozoans are commonly known as true jellyfishes, for the medusa form is larger and better known than the polyp form. In hydrozoans, the polyp phase is more conspicuous than the medusa phase in groups such as hydroids and hydrocorals. Hydromedusae are smaller and more delicate than scyphomedusae or cubomedusae, and may be completely absent from the life cycle of some hydrozoan species. Cubozoans have medusae commonly known as box jellyfish, from their shape. Some of these are responsible for human fatalities, mostly in tropical Australia and Southeast Asia, and include the so-called sea wasps. The polyp is tiny and inconspicuous.

Many cnidarian polyps are individually no more than a millimetre or so across. Polyps of most hydroids, hydrocorals, and soft and hard corals, however, proliferate asexually into colonies, which can attain much greater size and longevity than their component polyps. Certain tropical sea anemones may be a metre in diameter, and some temperate ones are nearly that tall. Anthozoans are long-lived, both individually and as colonies; the life span of both large and small sea anemones has been estimated on the order of centuries. All medusae and sea anemones occur only as solitary individuals. Scyphomedusae can weigh more than a ton, whereas hydromedusae are, at most, a few centimetres across. Tentacles of medusae, however, may be numerous and extensible, which allows the animals to influence a considerably greater range than their body size might suggest. Large populations of hydroids can build up on docks, boats, and rocks. Similarly, some medusae attain remarkable densities—up to thousands per litre of water—but only for relatively brief periods.

Individuals and colonies

Distribution and abundance. Many of the world's benthic (bottom-dwelling) ecosystems are dominated by anthozoans. Although soft and hard corals coexist in virtually all tropical areas appropriate for either, coral reefs of the tropical Indo-Pacific are built mainly by members of the anthozoan order Scleractinia (hard corals); whereas on coral reefs of the Caribbean members of the anthozoan subclass Alcyonaria (soft corals) are much more prominent. Aside from being the most numerous and covering the greatest area of any animals on the reef, the corals structure their environment, even after death. Soft corals contribute greatly to reef construction by the cementing action of the skeletal debris (spicules), filling in spaces between hard coral skeletons.

Coral reefs

Soft-bodied anthozoans are similarly dominant in other seas. Temperate rocky intertidal zones in many parts of the world are carpeted with sea anemones. They sequester the space that is therefore made unavailable to other or-

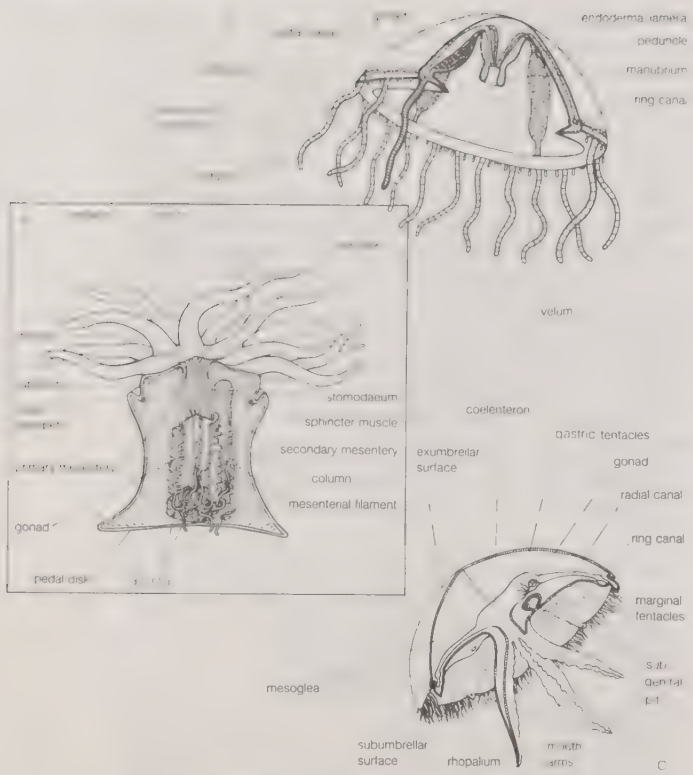

Figure 1: *Structure of cnidarians.*

ganisms, thus having a profound impact on community structure. The curious hemispherical anemone *Liponema* is the most abundant benthic invertebrate in the Gulf of Alaska, in terms of numbers and biomass. Parts of the Antarctic seabed are covered by anemones, and they occur near the deep-sea hot vents.

Importance. Prominent among organisms that foul water-borne vessels are sedentary cnidarians, especially hydroids. The muscles that make scyphomedusae strong swimmers are dried for human consumption in Asia. Sea anemones are eaten in some areas of Asia and North America.

Uses of corals

Throughout the tropics where reefs are accessible, coral skeletons are used as building material, either in blocks or slaked to create cement. Another use for cnidarian skeletons is in jewelry. The pink colour known as "coral" is the hue of the skeleton of a species of hydrocoral. Other hydrocorals have purplish skeletons. Skeletons vary in hue, and those considered most desirable command a high price. The core of some sea fans, sea whips, and black corals are cut or bent into beads, bracelets, and cameos.

All cnidarians have the potential to affect human physiology owing to the toxicity of their nematocysts. Most are not harmful to humans, but some can impart a painful sting—such as *Physalia,* the Portuguese man-of-war, and sea anemones of the genus *Actinodendron.* These, and even normally innocuous species, can be deadly in a massive dose or to a sensitive person, but the only cnidarians commonly fatal to humans are the cubomedusae, or box jellyfish. Anaphylaxis (hypersensitivity due to prior exposure and subsequent sensitization) was discovered with experiments on *Physalia* toxin. Extracts of many cnidarians, mostly anthozoans, have heart-stimulant, antitumour, and anti-inflammatory properties.

NATURAL HISTORY

Reproduction and life cycles. All species of cnidarians are capable of sexual reproduction, which occurs in only one phase of the life cycle, usually the medusa. Many cnidarians also reproduce asexually, which may occur in both phases. In asexual reproduction, new individuals arise from bits of tissue that are budded off from a parent, or by a parent dividing lengthwise or crosswise into two smaller individuals. Polyps that remain physically attached to one another or embedded in a common mass of tissue constitute a colony. In some colonies, polyps share a common coelenteron through which food captured by any member is distributed to others. Hydrozoan polyp colonies, called hydroids, are prostrate, bushy, or feathery in form. Examples of other colonies are anthozoan soft corals and most reef-forming hard corals. Polyps that are produced asexually and then physically separate are called clones.

Budding

Although genetically identical, colony members of many hydrozoans and some anthozoans are polymorphic, differing in morphology (form and structure) and/or physiology. Each zooid within the colony has a specific function and varies somewhat in form. For example, gastrozooids bear tentacles and are specialized for feeding. Some colonies possess dactylozooids, tentacleless polyps heavily armed with nematocysts that seem primarily concerned with defense. Gonozooids develop reproductive structures called gonophores. Members of the order Siphonophora, free-floating colonial hydrozoans, display an even greater variety of polymorphs. These include gas-filled floats called pneumatophores, pulsating, locomotory structures called nectophores, and flattened, protective individuals called bracts or phyllozooids.

Although the medusa stage is absent in anthozoans, polyps produce additional polyps sexually and, in some species, asexually as well. Hydromedusae are budded from polyps that, in some colonial species, are specialized for this function. The major distinguishing feature of the cubozoans is that each polyp transforms entirely into a medusa. In most scyphozoans, a scyphistoma (scyphopolyp) produces immature medusae (ephyrae) by asexual fission at its oral end. This process, called strobilation, results in eight-armed, free-swimming ephyrae.

Differentiation of gametes

Gametes differentiate in parts of the body referred to as gonads, despite the fact that cnidarians cannot be said to have true ovaries and testes because they lack organs. In anthozoans, cubozoans, and scyphozoans, gametes develop in the endoderm, whereas in hydrozoans they ripen in the ectoderm, although they do not necessarily originate there. Sexes are commonly separate, but hermaphroditism

From R.D. Campbell, "Cnidaria" in A.C. Giese and J.S. Pearse (eds.), *Reproduction of Marine Invertebrates vol. 1: Acoelomate and Pseudocoelomate Metazoans* (1974), Academic Press

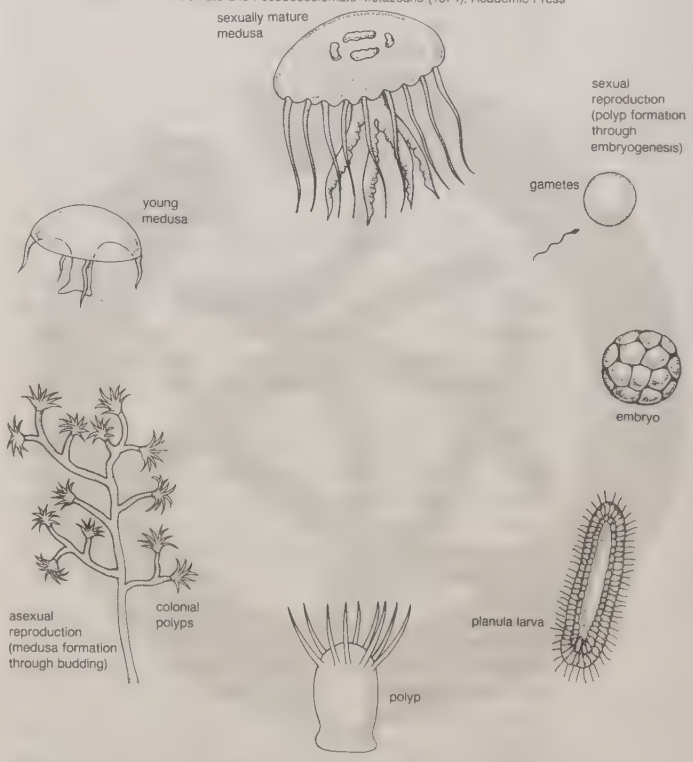

Figure 2: Life cycle of cnidarians showing the medusa and polyp stages. Not all cnidarians follow the life cycle exactly, and variation for some species is indicated by broken lines.

is known. Some hermaphroditic species are capable of self-fertilization. Gametes are generally shed into the sea, where the eggs are fertilized. Cleavage produces a ciliated ball of cells that elongates and develops a tuft of cilia at one end to become a planula larva, which may be free-swimming and planktonic, or crawling and benthic. Its ciliated tuft, which may have sensory abilities, is directed forward in locomotion. After a motile period, the planula attaches by its forward end to a solid object and develops tentacles around its posterior end, thereby transforming into a polyp. In some anthozoans and a few scyphomedusae, eggs are fertilized without being released. Embryonic development passes either partly or entirely within the mother's coelenteron or, as in the case of some anemones and some members of the anthozoan subclass Alcyonaria (octocorals), attached to the outside of her body. In some species of hydroids that lack a free medusa stage, eggs are fertilized and the embryo develops in specialized zooids that are essentially attached medusae. Such brooding species may release offspring as very advanced larvae or as miniature adults, so that a planktonic stage is absent from the life cycle.

Ecology and habitats. Most polyps require solid substrata for attachment, although a few burrow into soft sediments, extending only their tentacular crowns above the surface (Figure 3). Polyps are abundant in shallow waters, but sea anemones can also occur in the deepest parts of the oceans. Medusae maintain a favoured depth in the water and are carried about by currents. Most hydromedusae and scyphomedusae live in surface waters, generally in bays and along coasts, but certain species are abundant in the open ocean.

The nematocysts of cnidarians restrict potential predators to a limited array of specialists. Nematocysts also allow cnidarians to prey on a variety of would-be competitors for space and food. Most species that are capable of monopolizing space reproduce predominantly asexually. A coral, for example, can cover an area rapidly and commonly has the ability to overgrow other organisms, including corals of other species. Clone-forming sea anemones of several species actively compete for space by killing others, primarily those of their own species. When members of one clone encounter those of another, the two combatants inflate and slap one another with nematocyst-studded fighting structures (acrorhagi) located below the tentacles. Attacks may result in the death of one of the anemones, or both may retreat. Tentacle touching is involved in the recognition of non-clonemates, which presumably is chemically mediated.

Competition for space

Cnidarians are not immune from predation. Hydroids are victimized by nudibranchs that bite through the chitinous skeleton or crawl into its openings. The crown of thorns starfish, *Acanthaster planci,* extrudes its stomach over a coral colony, releases digestive enzymes, and then absorbs the liquified tissue. Butterfly and parrot fishes eat corals, being insensitive to the effects of nematocysts, which is also true of marine turtles that feed on pelagic scyphomedusae.

Locomotion. Medusae swim by jet propulsion (see below *Tissues and muscles*); however, most do so weakly and are carried passively by currents over long distances. Polyps are generally sedentary. Pennatulacean colonies move slowly across soft substrata by action of their inflatable peduncle (a stalk that attaches to the strata in the lower end and to the polyp body on the higher end). Sea anemones that are attached to firm substrata can creep slowly on their pedal disks or detach altogether, often in response to unfavourable physical conditions or to attack by predators. When provoked by certain starfish and nudibranchs, individuals of a few anemone species swim by paddling their tentacles or flexing their columns.

Food and feeding. All cnidarians are carnivores. Most use their cnidae and associated toxin to capture food, although none is known actually to pursue prey. Sessile polyps depend for food on organisms that come into contact with their tentacles. Some, such as colonial corals with minute polyps, feed on particulate material gathered in mucus impelled to the mouth by cilia (microscopic hairlike projections of cells capable of beating or waving). A hydromedusa alternately swims upward and sinks: on the upward course, its trailing tentacles are not apt to encounter food organisms, but in sinking, the extended tentacles "fish" through the water, capturing food. Once a food item is captured, tentacles move it to the mouth, either by bending in that direction or by passing it to tentacles nearer the mouth. The mouth opens, the lips grasp the food, and muscular actions complete swallowing.

Carnivorous habits

The edges of the mouths of some scyphomedusae are elaborated into mouth arms that trail behind the slowly swimming jellyfish, presenting huge surfaces for food gathering. The mouth of a scyphomedusa of the order Rhizostomae is subdivided into thousands of minute pores that lead by tubes to the coelenteron. Each pore is associated with an external ciliated gutter that collects minute organisms and detrital material as the medusa rests mouth-upward on the sea bottom.

Pink, orange, red, and brown cnidarians are commonly pigmented by carotenoids derived from crustaceans in their diet. Endodermal cells of some corals, medusae, hydras, and sea anemones contain single-celled golden-brown algae (dinoflagellates), called zooxanthellae, or green algae, called zoochlorellae. The carnivorous cnidarians cannot digest these algae but do derive a variety of nutrients from them, including glucose and oxygen. Carbon dioxide produced in respiration may be used by the algae in photosynthesis.

Zooxanthellae and zoochlorellae

Associations. Cnidarians enter into complex associations with a variety of other organisms, including unicellular algae, fishes, and crustaceans. Many of these relationships, such as those with zooxanthellae and zoochlorellae, are mutualistic symbioses—*i.e.,* relationships benefiting both partners. Reef-forming corals, which possess zoox-

anthellae, form more substantial skeletons than do non-reef-forming corals, which lack zooxanthellae, for reasons that are not understood but are related to the algae. Many corals are so dependent on zooxanthellae that they cannot live in prolonged darkness, which is why coral reefs develop only in shallow, well-illuminated waters.

There are species of sea anemones that live on gastropod shells inhabited by hermit crabs, a type of crustacean that must change shells as it grows. Some hermit crabs move the anemones with them from the old shells to the new. In other cases, the anemones take the initiative, somersaulting from a now-empty shell onto the newly obtained one. A few deep-sea anemones form the shells in which their crabs dwell. This adaptation eliminates the need to change shells, but the death of one partner probably results in the death of the other. Certain true crabs carry anemones on their backs and legs, or even in their claws. These associations benefit the anemone by providing it with transport, and sometimes it can steal food from its crustacean partner. In turn, the sea anemone protects its host from predators such as octopuses and other crabs.

Gastropods (of the phylum Mollusca) also associate with cnidarians. Among the most remarkable are the nudibranchs that eat anemones and hydroids and then sequester certain types of immature, undischarged cnidae from the prey. Once the cnidae have matured within the nudibranch, they can be used in its own defense.

Symbiosis with fishes

One of the best known cnidarian symbioses is the mutualism between 10 species of tropical anemones and 26 species of anemone fish (such as the clown fish). These fishes live within the protective field of anemone tentacles, where they take refuge when a predator threatens. Immunity of the fishes to the stings of the nematocytes results from the thin layer of mucus that covers their bodies. It is unclear whether the mucous is made by the fishes themselves, or acquired by contact with the anemone's tentacles. Without its mucus, the clown fish, like any other small fish, may be stung to death and eaten by the anemone. Anemone fishes serve their hosts by driving away fishes that prey on anemones. Other fishes have a similar association with large medusae.

FORM AND FUNCTION

Tissues and muscles. Cnidarians consist of two cell layers: an outer ectoderm and an inner endoderm that lines the coelenteron. Between these is sandwiched the mesoglea, a largely noncellular layer composed of a jellylike material permeated by a complex network of supporting fibres that may be microscopically thin or very thick. The fibres and jelly are elastic. In medusae, mesoglea comprises the bulk of the animal and forms a resilient skeleton. In polyps, the water-filled coelenteron acts as a hydrostatic skeleton, which, in concert with the mesoglea, maintains the form of these animals.

Muscles in cnidarians are extensions of the bases of ectodermal and endodermal cells. Individual muscle cells are relatively long and may occur in dense tracts in jellyfish or sea anemones. Most cnidarian muscles, however, are thin sheets at the base of ectodermal and endodermal layers.

Ectodermal and endodermal muscles

In polyps, ectodermal muscles are oriented lengthwise along the cylindrical body and tentacles; endodermal ones are usually circular. Contraction of circular muscles against coelenteric fluid causes the polyp's body to elongate; contraction of longitudinal muscles causes it to shorten. Similar layers of muscles extend and contract the tentacles. Bending results from unequal contractions of longitudinal muscles on opposite sides of the body.

In medusae, all muscles are ectodermal, restricted to the concave oral surface (subumbrellar surface), and organized into circular and radial tracts. Contraction of circular muscles squeezes the subumbrellar space, forcing out contained water and causing the medusa to move by jet propulsion. Recovery of the elastic mesoglea re-extends contracted muscle fibres. Radial muscle contraction distorts the bell, directing the water jet at angles to the longitudinal axis of the bell, allowing the medusa to steer.

Support mechanisms and skeletons. Most members of what is usually considered a soft-bodied group have some sort of skeleton aside from the hydrostatic system described above. Both external and internal skeletons occur in the phylum, but only among polyps.

External skeleton

Most hydroid polyps secrete a horny, chitinous external skeleton that is essentially a tube around the polyp and the network of stolons that interconnect members of a colony. As well as being protective, it confers stiffness for support and has joints for flexibility. A few scyphozoan polyps have comparable chitinous skeletons. Unlike those of hydroids, hydrocoral skeletons are composed of calcium carbonate and are internal by virtue of being shallowly penetrated by channels of living tissue. Hydrocorals, which include the order Milleporina (millepores), commonly called fire coral, and the precious red coral used for jewelry, form encrusting or branching skeletons similar to those of anthozoan corals.

An anthozoan coral polyp, which resembles a sea anemone, can nearly completely retract into the calcareous cup it secrets around itself. This external skeleton underlies a continuous, superficial layer of tissue. Non-reef-forming corals typically are solitary or form small, rather delicately branched colonies, their polyps being relatively large and widely spaced. In some species of reef-forming corals, polyps are so tightly packed that their individual units share common walls. Skeletons may be encrusting, massive, or arborescent (treelike). The latter type of skeleton is delicate and typical of quiet waters at depth or in lagoons, while the former two predominate where water motion is strong. Skeleton is laid down in massive corals at a rate of about one centimetre per year; branching corals may grow considerably more rapidly. The largest corals represent cooperative efforts of up to 1,000,000 tiny individuals precipitating calcium carbonate over centuries. Few attain such proportions, however, and even the largest are eventually broken down by boring organisms such as algae, worms, sponges, and barnacles, as well as by physical processes.

Internal skeleton

The last major category of cnidarian skeletons, formed by the anthozoan subclass Alcyonaria and the order Antipatharia, are internal. Sea fan and sea whip skeletons consist of the horny protein gorgonin with calcareous spicules fused to form a solid or jointed central rod. Soft coral spicules are discrete, mostly microscopic objects of diverse shapes that vary from needle-like to club- and anchor-shaped. Located in the ectoderm, spicules stiffen the colony. In some species the several spicules that form a protective cup around each polyp may be several millimetres long. The alcyonarian *Tubipora* is known as the organ-pipe coral after the form of its red calcareous skeleton. Blue corals (the order Helioporacea) have skeletons of crystalline calcareous fibres fused into sheets, which are used for jewelry. Colonies of black coral resemble bushes and may stand more than three metres tall. Their skeletons, made entirely of proteinaceous material similar to gorgonin, are likewise used for jewelry.

Sea anemones do not produce skeletons, although their close relatives in the order Zoanthinaria incorporate foreign objects (sand grains, sponge spicules) into their body walls, which gives them rigidity and toughness. Small anemones that live high in the intertidal zone commonly inhabit abandoned barnacle tests (shells), thereby acquiring some of the benefits of a skeleton.

Nervous system and organs of sensation. Medusae have a more highly developed nerve net than do polyps, a feature that is associated with the more active way of life of medusae. Swimming is coordinated by the nervous system. Nervous systems that are capable of conducting nerve impulses both quickly and slowly give these animals considerable behavioral responsiveness and flexibility. Ganglia or other accumulations of nerve cell bodies are not found in cnidarians, but there are gap junctions between neurons and between neurons and effectors, which allow the transmission of nerve impulses. Statocysts, located between the tentacles or near the tentacular base, inform the animal of its orientation with respect to gravitational forces. Light-sensitive ocelli (external patches of pigment and photoreceptor cells organized in either a flat disk or a pit) occur in some medusae of each of the three classes that possess this stage. Such sensory structures are closely associated with a nerve net.

Nerve net

In the past nematocysts were considered independent effectors: that is, they were thought to fire upon appropriate stimulation, without mediation by the nervous system. Evidence, however, favours there being some organismal control over their firing, which may consist only of adjusting the threshold for firing, or the selectivity. Some scientists believe that nervous complexes associated with batteries (groups) of cnidae are the mechanism of control.

Extracellular and intracellular digestion

Digestion, respiration, and excretion. Food is taken in and wastes are discharged through the mouth. Extracellular digestion occurs in the coelenteron, which has, in all except hydrozoans and some tiny members of the other classes, radial projections of the wall into the coelenteron that increase the surface area. Ingested material is broken down somewhat in the coelenteron and then taken up by endodermal cells for final intracellular digestion.

Respiration and excretion in cnidarians are carried on by individual cells that obtain their oxygen directly from water—either that in the coelenteron or that of the environment—and return metabolic wastes to it. Thus, all physiological functions are carried out at no more than the tissue level of differentiation.

Defense and aggression: nematocysts. Cnidae range from about 10 micrometres (.0004 inch) to 100 micrometres in length. Each consists of a spherical or cigar-shaped capsule with an eversible, hollow tubule extending from one end. In the unfired state, the tubule is coiled within the capsule. When a cnidarian contacts a predator or prey item, the capsule opens and the tubule everts. The tubule may be adhesive, or it may entangle the object. Both types serve to hold food items. A third type of tubule is armed with spines that penetrate predator or prey. Toxins contained in the capsule are injected through the tubule into the object being held. Each cnida can be fired only once. Undifferentiated interstitial cells of the ectoderm and endoderm appear to be the source of the cnidoblasts (cells that produce cnidae).

EVOLUTION

Theories of evolution

Among theories proposed on the evolution of the phylum Cnidaria, most treat the radial symmetry and tissue level of organization as evidence that the group is primitive and hold that the medusa is the original body form, being the sexually reproductive phase of the life cycle. Another theory is that the original cnidarian was a planula-like organism that preceded both polyp and medusa. In either case, Hydrozoa is considered to be the most ancient of cnidarian classes, and Trachylina is thought to be the most primitive extant order of that group. An alternative view is that anthozoans are the stem of the phylum, which evolved from bilateral flatworms and is secondarily simplified. A corollary to this theory is that the polyp is the ancestral body form.

Speculations about the origin of the phylum are not easily resolved, for preservable skeletal structures developed relatively late in cnidarian evolution. The oldest fossilized cnidarians were soft-bodied. Representatives of all four modern classes have been identified in Ediacaran fauna of the Precambrian Period (570,000,000 years ago) known from more than 20 sites worldwide. As much as 70 percent of Ediacaran species have been considered to be cnidarians. Curiously, there are few fossil cnidarians of the Cambrian Period (570,000,000 to 500,000,000 years ago). The Conulariida, which existed from the Cambrian Period to the Triassic Period (225,000,000 to 190,000,000 years ago) are considered by some scientists to be skeletal remains of scyphopolyps, either ancestral to the coronates or without modern derivatives. Presumed fossil sea anemones are found in the early Cambrian Period. Colonies of Stromatoporoidea, considered to be an order of the class Hydrozoa that extended from the mid-Cambrian Period to the Cretaceous Period (136,000,000 to 65,000,000 years ago), produced massive skeletons. Although there were two groups of Paleozoic corals, neither of which has modern descendants, they were not great reef-builders during that era. Scleractinians arose in the mid-Triassic Period; blue corals, gorgonians, millepores, and hydrocorals have records from the Jurassic Period (190,000,000 to 136,000,000 years ago) or the Cretaceous Period to the present. Most other cnidarians are known only from the Holocene Epoch (within the last 10,000 years).

CLASSIFICATION

Annotated classification. The following classification, limited to living cnidarians, generally follows that used by D.G. Fautin in S.P. Parker (ed.), *Synopsis and Classification of Living Organisms,* vol. 1 (1982), and L.H. Hyman, *The Invertebrates,* vol. 1, *Protozoa Through Ctenophora* (1940).

PHYLUM CNIDARIA (COELENTERATA)

Nematocyst-bearing, radial metazoans without organs. Have a cellular inner endoderm and outer ectoderm, separated by noncellular mesoglea. Polyp and medusa forms; either or both may be present in one life history. Most polyps have tentacles around mouth; tentacles of medusae at bell margin. One internal cavity, the coelenteron, has 1 opening to exterior, the mouth. About 9,000 species.

Class Anthozoa

Exclusively polypoid with biradial symmetry. Oral end a disk with central mouth and hollow tentacles arising at margin and/or on surface. Mouth leads to coelenteron via stomodaeum that has ciliated troughs (siphonoglyphs) for water transport into and out of coelenteron. Coelenteron divided by radial mesenteries that extend inward and insert on the stomodaeum (complete mesenteries) or not (incomplete mesenteries). About 6,000 species.

Subclass Alcyonaria

Octocorals. Polyps with 8 pinnately branched tentacles, 8 mesenteries, and a single siphonoglyph. Nearly all colonial with internal skeletons.

Order Stolonifera. Polyps of colony connected by stolons. Skeletons of spicules or horny external cuticle. Shallow tropical and temperate seas.

Order Telestacea. Long axial polyps bear lateral polyps. Skeleton of spicules fused with a horny material. Tropical.

Order Gorgonacea. Sea fans and sea whips. Colonies commonly arborescent with axial skeleton of gorgonin and/or calcareous spicules. Polyps rarely dimorphic. Tropical and subtropical.

Order Alcyonacea. Soft corals. Small to massive colonial forms. Lower parts of polyps fused into a fleshy mass; oral ends protrude. Internal skeleton of isolated calcareous spicules. Primarily tropical.

Order Helioporacea (*Coenothecalia*). Blue coral. Massive lobed calcareous skeleton. Tropical; 1 Caribbean and 1 Indo-West Pacific species.

Order Pennatulacea. Sea pens and sea pansies. Fleshy, always dimorphic, unbranched colonies, with 1 axial polyp and many lateral ones. Polyp-free peduncle burrows into soft sediments; polyp-bearing distal end of the polyp (rachis) extends into water and may be completely retractile. Central skeleton a calcified axial rod; polyps and rachis have isolated calcareous spicules.

Subclass Ceriantipatharia

Black corals and tube anemones.

Order Antipatharia. Black coral. Large bushy colonies with thorny, hornlike axial skeleton formed by small polyps with 6 simple tentacles and 1 siphonoglyph. Mostly tropical and subtropical.

Order Ceriantharia. Tube anemones. Solitary polyps with 2 sets of tentacles (oral and marginal) that form feltlike tubes of specialized cnidae (ptychocysts) and burrow in soft sediments. Shallow waters worldwide.

Subclass Zoantharia

Sea anemones and corals. Six (or multiples of 6) tentacles (rarely branched). Mesenteries commonly arranged hexamerously. Solitary or colonial. Skeletons non-spicular calcareous, horny, or lacking. Usually 2 siphonoglyphs.

Order Actiniaria. Sea anemones. Solitary or clonal, never colonial; lacking skeleton; with or without basilar muscles. Mostly littoral or benthic, commonly attached to firm substrata but some burrow in soft sediments. Worldwide.

Order Corallimorpharia. Sea-anemone-like solitary or aggregated polyps lacking basilar muscles and skeleton. Coral-like muscles and nematocysts. Mostly tropical.

Order Ptychodactiaria. Sea-anemone-like, lacking ciliated tract on edge of mesenteries and basilar muscles. Both poles.

Order Scleractinia (*Madreporaria*). True or stony corals.

Mostly colonial; calcareous external skeleton; no basilar muscles or siphonoglyphs. Mostly tropical and subtropical.

Order Zoanthinaria (*Zoanthidea*). Solitary, clonal, or colonial polyps resembling sea anemones. Lack skeleton but may incorporate debris into body wall, commonly epizoic. One complete and 1 incomplete mesentery per pair. Mostly tropical.

Class Cubozoa

Tropical, cuboidal medusae that swim strongly; box jellyfishes. Margin simple with single or grouped tentacles arising above the 4 corners. Polypoid stage of most species unknown. Fiercely stinging members can cause human fatalities. Contains 1 order. Cubomedusae.

Class Hydrozoa

Life histories may involve both polypoid and medusoid stages, but either may be suppressed or absent. Tetramerous or radially symmetrical medusae small, with shelf of tissue (velum) across lower part of bell, which reduces diameter of subumbrellar aperture (condition known as craspedote). Colonial forms commonly polymorphic. Coelenteron undivided. Gametes ripen in ectoderm. Only class with some freshwater members. 2,700 species.

Order Actinulida. Curious group of solitary, motile cnidarians with features of both polyps and medusae. Europe; in marine sand.

Order Chondrophora. Floating polymorphic colonies supported by chitinous skeleton. Free medusae are produced; includes *Velella*. Oceanic; worldwide.

Order Hydroida. Hydroids. Usually colonial and polymorphic; release free medusae or retain modified medusoid reproductive structures on polyp colony. Polyps usually have a chitinous exoskeleton. Includes naked, solitary freshwater polyp *Hydra*. Largest order of Hydrozoa.

Suborder Anthomedusae. Medusae bell-shaped, with gonads on the stomach or sides of manubrium. Sensory structures consist of pigmented eyespots (ocelli). Skeleton, if present, lacks cup (hydrotheca) into which polyp may withdraw (a condition known as gymnoblastic); few species with calcareous exoskeleton. Most abundant in bays and shallow coastal waters.

Suborder Leptomedusae. Medusae saucer-shaped, but lacking in many species. Gonads on radial canals. Sensory structures usually statocysts. Hydroids with hydrothecae (condition known as calyptoblastic). All shallow marine waters.

Suborder Limnomedusae. Small medusae with gonads on stomach walls or radial canals. Polyps solitary or colonial, commonly with 1 or 2 tentacles, and no skeleton. Mostly freshwater.

Order Milleporina. Fire coral. Colonial forms producing massive calcareous skeletons. Gastrozooids and dactylozooids project through pores in surface of skeleton. Reduced, acraspedote (lacking a velum) nonfeeding medusae are released. Tropical.

Order Siphonophora. Pelagic polypoid colonies with greatest degree of polymorphism in phylum; lack medusae. Oceanic; worldwide. Includes Portuguese man-of-war, *Physalia*.

Order Stylasterina. Hydrocorals. Resembling millepores; colonies erect and branching or prostrate. Commonly yellow, red, or purple. Reduced medusae not freed; develop and produce gametes in cavities of skeleton (ampullae). Worldwide; includes precious red coral, *Corallium*.

Order Trachylina. Medusa dominant; reduced or no polyp stage. Statocysts and special sensory structures (tentaculocysts). Differ from other hydromedusae by having tentacles inserted above umbrellar margin. Oceanic, mostly warmer waters.

Suborder Laingiomedusae. Medusae with features of both Narcomedusae and Trachymedusae. Polyp unknown.

Suborder Narcomedusae. Scalloped margin; gonads on stomach walls. Manubrium lacking.

Suborder Trachymedusae. Smooth bell margin; gonads on radial canals arising from the stomach. Polyp and asexual reproduction absent.

Class Scyphozoa

Exclusively marine group in which acraspedote medusae predominate. Life histories commonly involve alternation of a very small polyp, the scyphistoma, with a medusa, which develops from an ephyra released by the polyp. Coelenteron of both divided by 4 longitudinal septa producing tetramerous radial symmetry. Gonads endodermal. Marginal sensory structures (rhopalia) with statocysts and/or ocelli. Most abundant in coastal waters, but oceanic species exist. About 200 species.

Order Coronatae. Large medusae that are conical, dome-shaped, or flattened, with furrow around bell above scalloped margin. Some species have scyphistoma stage with external chitinous skeleton. Oceanic, some species living at great depths.

Order Rhizostomae. Medusae like those of Semaeostomeae but with mouth subdivided into minute pores that connect with coelenteron. Mostly tropical. Deep-water species may lack polypoid stage.

Order Semaeostomeae. Most common and best known jellyfishes. Full alternation of polyp and medusa stages. Bell domed or flattened, with the margin scalloped into 8 or more sections. Edges of single mouth drawn out into 4 long arms. Most species in warm, coastal waters, a few in frigid waters; some oceanic. Includes the giant *Cyanea arctica*, which may attain 2 m in diameter.

Order Stauromedusae. Sessile jellyfish that are vase-, goblet-, or trumpet-shaped, and usually bear 8 groups of tentacles. No more than 2–3 cm long. Apparently lacking polypoid stage. Temperate and cold temperate waters worldwide.

Critical appraisal. The classification of living cnidarians is relatively stable and generally accepted. One unanswered question relates to their evolutionary position among the lower Metazoa (a division of the animal kingdom that includes all phyla except the Protozoa). Members of the small phylum Ctenophora (comb jellies, sea walnuts) are superficially similar to medusae, having a gelatinous body with one opening, and tentacles. The one species of Ctenophora possessing nematocysts had been thought to link the phyla. Mills and Miller have shown that members of the phylum Ctenophora obtain their cnidae by preying on a medusa, and the similarity in body form is considered convergence due to the pelagic way of life.

Anthozoa is a well-defined, coherent group, but relationships among its components are poorly understood, and the ranking of some of them is disputed. Some regard corallimorpharians as scleractinians that lack a skeleton. Similarity of larval ceriantharians to antipatharian polyps is the rationale for subclass Ceriantipatharia. Morphology of antipatharians is, however, in some ways, nearer that of alcyonarians than of zoantharians, and alternative schemes place Antipatharia in subclass Alcyonaria. Ceriantharia, too, sits uncomfortably in Zoantharia, although it bears no special relationship to the Alcyonaria. It is generally viewed as a divergent, early offshoot of the anthozoan line. Treatment of both Antipatharia and Ceriantharia as distinct subclasses of Anthozoa not particularly closely related to one another might better express their evolutionary relationships.

Many cnidarian biologists continue to regard Cubozoa as an order of Scyphozoa. Cubozoans have features of both Scyphozoa and Hydrozoa, but the complete metamorphosis of polyp into medusa supports its placement in a class intermediate between the other two.

Hydrozoan suborder Limnomedusae is not accepted by some workers, and the groups assigned to it are treated as members of the other suborders. In substantial ways, characters of many Limnomedusae bridge the differences between the Anthomedusae and the Leptomedusae. The hydrozoan order Chondrophora has morphological characteristics suggesting that the group might be better treated as part of Anthomedusae than as a discrete order.

BIBLIOGRAPHY. The standard technical treatment of the Cnidaria is LIBBIE HENRIETTA HYMAN, *The Invertebrates*, vol. 1, *Protozoa Through Ctenophora* (1940). The history of the phylum as deduced from the fossil record is covered in RAYMOND C. MOORE (ed.), *Treatise on Invertebrate Paleontology*, part F, *Coelenterata* (1956, reprinted 1967). C.E. MILLS and R.L. MILLER, "Ingestion of a Medusa (*Aegina citrea*) by the Nematocyst-Containing Ctenophore *Haeckelia rubra* (formerly *Euchlora rubra*): Phylogenetic Implications," *Marine Biology*, 78(2):215–221 (1984), offers information on the relationship between Ctenophora and Cnidaria. The following proceedings of international symposia on cnidarians provide useful information: W.J. REES (ed.), *The Cnidaria and Their Evolution* (1966); TAKASI TOKIOKA and SABURŌ NISHIMURA (eds.), *Recent Trends in Research in Coelenterate Biology* (1973); G.O. MACKIE (ed.), *Coelenterate Ecology and Behavior* (1976); and P. TARDENT and R. TARDENT (eds.), *Developmental and Cellular Biology of Coelenterates* (1980). Coins and Coinage

The use of cast-metal pieces as a medium of exchange is very ancient and probably developed out of the use in commerce of ordinary ingots of bronze and other metals that possessed an intrinsic value. Until the development of bills of exchange in medieval Europe and paper currency in medieval China, metal coins were the only such medium. Despite their diminished use in most commercial transactions, coins are still indispensable to civilized economics; in fact, their importance is growing as the result of the widespread use of coin-operated machines. The term numismatics (from the Latin *numisma* and Greek *nomisma*, "coin") denotes the study of coins, including medals but excluding seals.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, Part Five, Division III, Section 533.

Numismatics

COINS AS HISTORICAL DATA

Being made in most ages of precious metal, or alternatively possessing a substantial token value, coins have always been prized, often hoarded, and, therefore, frequently buried for safety. The contents of such savings banks have been dug up in all ages, so that the coins of past civilizations continue to be found in vast numbers. Studied alongside literary or archaeological evidence, they yield a wide range of information that is especially valuable for chronology and economic history. Coins may reflect the wealth and power of cities and states, and study of their distribution may help to define the physical extent of territorial dominion or to illustrate major commercial connections. Thus, the popularity in ancient times of Athenian silver tetradrachms (coins worth four drachmas, the drachma having a unit weight of about 4.25 grams) in the Levant and of Corinthian silver staters (ancient Greek coins of various weight standards) in Magna Graecia (in southern Italy) testifies to established trade links; finds of early Roman imperial gold in India corroborate the reference of the Roman historian Pliny the Elder to the drain on Roman gold to pay for Indian and other Eastern luxuries; and huge finds of Arab silver coins in Scandinavia show the extent of trade, in particular the demand for furs by the ʿAbbāsid caliphs and the Sāmānid rulers of Iran. One result of such widespread commercial contacts is that certain currencies acquired special international preeminence. In ancient times, those of Athens, Corinth, and Philip II of Macedon were widely popular; so, in medieval times, were the gold dinars (a term derived from the Roman denarius) of the early caliphs and the gold ducats of Florence and Venice, while in modern times the silver dollars of Mexico and Maria Theresa of Austria and the gold sovereigns of Great Britain played a similar role. Moreover, the study of depreciation and debasement of coinage may illuminate past national financial distress; the heavily alloyed 3rd-century-AD Roman antoniniani (coins introduced by the Roman emperor Antoninus, originally

Internationally preeminent currencies

having a value of two denarii) tell their tale as clearly as the depreciating paper currency of Germany in and after 1919.

No less valuable than the economic evidence yielded by a comparative study of coins is their purely documentary importance. Together with medals, they present an unrivaled series of historical portraits from the 4th century BC to the present day, many of them otherwise unknown, like the Greco-Bactrian kings or certain usurpers during the Roman Empire. Greek coinage is a particularly notable contribution to the history of art, displaying not only the beauty and strength of many artistic traditions but also (like Roman coinage) the miniature likenesses of numerous large-scale sculptural and architectural works now lost. The imperial coinage of Rome, apart from its portraiture, is important above all for the remarkable detail of its chronological and political content; and from both Greek and Roman coins much can be learned of mythology and religion. The Christian influences active in medieval Europe can be similarly measured from medieval currencies.

The principal metals of which ancient coins were made were electrum (an alloy of silver and gold), gold, silver, copper, brass, and bronze—all of them more or less proof against decay. Their use at first was generally dictated by availability. The earliest coins of Asia Minor were of electrum, a natural alloy (later produced artificially) washed from Lydian rivers; gold became the major currency metal of southwestern Asia as a whole, being derived from Scythian, Pontic, and Bactrian sources. The city-states of the Greek mainland preferred the silver that adjacent mines supplied, and the mines of Italy led to the choice of bronze for the earliest coinage of Rome. With the development of internal economies and external trade, gold, silver, and copper or bronze quickly came to be used side by side; Philip II of Macedon popularized gold in Greece, and gold, together with silver, competed strongly with copper in the Roman imperial currency, becoming paramount in the Byzantine and Arab empires and in the great commercial currencies of the Italian republics of the 13th century onward. Silver, however, was nearly always powerful in Roman currency and was the major coinage metal of Europe from the 8th to the 13th century. Bronze or copper was first used for small change in Greece from the late 5th century BC and in the Roman and Byzantine systems as well; the vast currency of China consisted of base metals down to modern times.

The metals of currency

The foregoing metals furnished most currencies until the early 20th century, when the appreciation in value of gold and silver and the need to economize led to the general production of paper currencies for the higher units of value, accompanied by token units of lower value expressed in terms of nickel (used, exceptionally, in Bactria in the 2nd century BC), cupronickel, bronze, and, in times of postwar stress, aluminum and aluminum bronze. Lead, which may easily decay, has seldom been used for coinage, except by the Andhras, inhabitants of the Deccan in ancient India; in pre-Roman Gaul; and in the more recent coinages of the Malay states. Iron, very occasionally used in antiquity—*e.g.,* in Sparta—reappeared in German coins of World War I. Zinc was employed by Rome as a constituent of fine brass coins and as an element in the alloy of a few Chinese coins from the 15th to the 17th century. Base metals furnished the material for some Celtic coins in Gaul and Britain in the last century BC. In crises, currencies have been produced from leather, cloth, card, paper, and other materials.

COIN COLLECTIONS AND SPECIALIST SOCIETIES

The enormous number of coins produced from earliest times has resulted in organized collecting over a long period. The continuous history of coin collecting begins with the Italian Renaissance, and Petrarch was characteristic of his time in forming a classical series. During the 15th and 16th centuries many collections were made by princes or nobles, for whom Greco-Roman coins possessed both moral and aesthetic appeal. Among the more famous cabinets were those of Jean, duc de Berry, of the d'Este family, of the emperor Maximilian I, and of Matthias Corvinus. The two last collections became the nuclei, respectively, of the present national collections of Austria and Hungary; later the cabinet of Louis XIV was to serve France similarly, just as that of the Stuarts might have served England but for its dispersal in the Puritan revolution.

In the 17th century numismatic scholars began to catalog and document existing collections. Italy possessed more than 350, France and the Low Countries about 200 each, and Germany not many fewer. The advent of scholarly numismatic compilations had important results. Distinction between the genuine and the spurious became surer; analytical syntheses based on detailed catalogs began to teach the principles of scientific numismatics; the recording of new material was all the more keenly undertaken; and the part played by numismatic evidence in historical reconstruction was increasingly understood.

From the 18th century onward it was therefore all the more important to collect on a scale at once wide and discriminating; and whether in charge of a royal cabinet, like the eminent Joseph Eckhel (1737–98) at Vienna, or the possessor of a splendid private collection, like William Hunter (1718–83) at Glasgow, the 18th-century collectors made a great contribution. Lesser collectors could also advance the science; their numbers were to grow in the 19th century with the output of authoritative catalogs (including the British Museum series from 1873) and informed handbooks. This growth was reflected in the foundation in many European countries of specialist societies responsible for scholarly publications. But the day of the great private collection was not yet done: superb cabinets were formed in the late 19th century, and those of Richard Lockett, Virgil Brand, and Emily Norweb in the 20th bore comparison with all except the great museum collections. In general, however, museums have taken over the main task of forming large collections; those of London, Oxford, Cambridge, Glasgow, Paris, Berlin, Vienna, Munich, Boston, and New York City are among the richest.

Specialist societies

London emerged as, and still remains, the world's largest numismatic market (followed by Zurich), serving the interests of public collections and private collectors in many lands. Inasmuch as these interests are, jointly, directed increasingly toward the systematic elucidation of historical and economic problems, international cooperation has become more important, being exercised through the International Numismatic Commission, itself associated with the International Committee for Historical Sciences. But below this apex there spreads out a vast body of private collectors in many lands, whose interests may often have been stimulated in childhood by the chance gift or discovery of a handful of coins.

History of coinage

ORIGINS

In both the East and the West, coinage proper was preceded by more primitive currencies, nonmonetary or semimonetary, which survived into the historic age of true coins, and may have derived originally from the barter of cattle, implements, and the like. The earliest currency of China of the 8th century BC consisted of miniature hoes and billhooks (pruning implements), with inscriptions indicating the authority. The small bronze celts (prehistoric tools resembling chisels) frequently found in hoards in western Europe probably played a monetary role. Even in modern times such mediums of exchange as fishhook currency have been known.

Metal has always achieved wide popularity as an exchange medium, being durable, divisible, and portable; and the origins of true coinage lie there. Ancient Egypt, which never developed a true coinage, was using gold bars of set weight from the 4th millennium BC; and a currency of gold rings was thereafter common. In the Middle East, also, gold rings long served the dual purposes of adornment and currency, supplemented by gold and silver bars from which segments could be cut. The choice of metal was, as usual, determined by availability. Around the Aegean Sea heavy talents (ancient units of weight and, later, of monetary value) of copper, ingots of 55 pounds (25 kilograms) or more, were in currency several centuries before true coinage, and the discovery of an iron bar with

a handful (*drachma*) of fractional iron spits (*obeloi*) dedicated in the Heraeum (a temple of the goddess Hera) at Argos, perhaps as part of King Pheidon of Argos' reforms of weights and measures in the 7th century BC, shows such currency continuing until historical times. Similar bundles of spits have been found elsewhere and are evidence of the desire to subdivide a cumbersome unit into smaller fractions for normal use. At the other end of the scale, there was, ultimately, the desire to express the value of a talent of copper or iron in terms of gold or silver; and Homer, who speaks of metal basins, tripods, and axes as gifts and prizes in a way that shows them as a recognized standard of wealth, also speaks of the talent of gold (*i.e.,* the value of a heavy base-metal talent expressed in a little pellet of gold). In Italy rough lumps of bronze (aes rude) formed a currency from early times, being succeeded by bars of regular weight; and Julius Caesar's record of the ancient British use of iron bars as currency (following his raids on Britain in 55 and 54 BC) is still borne out by not infrequent finds.

"Heavy" currencies

Such "heavy" currencies, mainly characteristic of European lands, show the employment of metals from which implements would normally be made. The impact upon this system of the gold of the East, and later of the silver of Greece, produced the need to value such metals in gold and silver, and this in turn resulted in the need to control and guarantee the quantity of gold and silver so used to avoid constant weighing. Once gold (and then silver) gained acceptance as conveniently small expressions of relatively high value, with a visible mark of guarantee, the stage of true coinage, as it first appeared in Asia Minor and India, had been reached. Not all lands, however, adopted true coinage: the easternmost fringes of the Greek world lacked it, and Carthage and Etruria were without coinage until the 5th century.

ANCIENT GREEK COINS

Early developments, c. 650–490 BC. True coinage began soon after 650 BC. The 6th-century Greek poet Xenophanes, quoted by the historian Herodotus, ascribed its invention to the Lydians, "the first to strike and use coins of gold and silver." King Croesus of Lydia (reigned *c.* 560–546 BC) produced a bimetallic system of pure gold and pure silver coins, but the foundation deposit of the Artemisium (temple to Artemis) at Ephesus shows that electrum coins were in production before Croesus, possibly under King Gyges. Croesus' earliest coins were of electrum, which the Greeks called "white gold." They were stamped on one side with the facing heads of a lion and a bull; this type was later transferred to his bimetallic series of pure gold and pure silver. (Some recent scholarship, however, suggests that this latter series was struck, in fact, under Croesus' Persian successors.)

The early electrum coinage consisted of small, thick, bean-shaped pieces, with a device stamped in relief on one side, the other being roughly impressed. Their intrinsic value fluctuated according to their gold and silver content; but the weight of the unit was fairly steady at about seven to eight grams, and the types stamped on them were the guarantee of authority.

Croesus' relations with Greece were close, and his bimetallic system may have owed something to the fact that Greece had itself now produced its first silver coins. The oldest are of Aegina, with, obverse, a turtle—associated with Aphrodite—and, reverse, an incuse square. Tradition—*e.g.,* in Julius Pollux, the 2nd-century-AD Greek scholar, and elsewhere—regarded these as struck by Pheidon of Argos in virtue of his supremacy over Aegina; but the coins are too late to claim association with him in Aegina. They began no earlier than the late 7th century, when Aeginetan maritime ascendancy was growing, incidentally spreading the Aeginetan weight standard for coinage, based on a drachma of about six grams, over much of the Peloponnese and also the Aegean, where similar currency was produced in the islands. Ambition and pride stimulated two neighbouring powers to strike their own coins. Corinth with its pegasi (from their constant obverse type of a pegasus) was coining silver from *c.* 575 with a light drachma of about three grams, and it is reasonably certain that in Athens, in the first half of the 6th century, Attic coins, based on a drachma of about 4.25 grams derived from Euboea and with a variety of obverse types, including an owl (the reverses, like those of the Corinthian pegasi, were impressed with a die design), were supplanting the earlier coinage of Aegina. These early silver coins, while much less valuable intrinsically than the electrum and gold coins of Asia Minor, nevertheless possessed considerable purchasing power: the Aeginetan and Attic-Euboic didrachms and the Corinthian tridrachm were high denominations suitable for major commerce and not for everyday life. For intercity transactions these staters (*i.e.,* standard units) were conveniently linked by the mina weight ($^1/_{60}$ of a talent) of 425 grams, made up by 150 Corinthian, 100 Attic, and 70 Aeginetan drachmas. Fractional pieces developed only slowly.

Between 550 and 500 commerce and civic pride had spread coinage to many parts of the Greek world. From the Persian Empire, with its vast gold and silver coinage, successor to that of Croesus, to Magna Graecia and Sicily, and from the Dorian colony of Cyrene to the Greek or semi-Greek cities of Thrace, there was a network of varied and competitive currencies, generally of fine quality and steady weight. Improved minting techniques began to affect their appearance. A second type, in relief, was substituted gradually for the roughly impressed reverse punch. The important effect of this on the development of coin types is well seen in the reorganized coinage of Athens from *c.* 525, in which the obverse bears the Athena head and the reverse the owl of Athens—religious patron and civic device; the monarch's head on an English penny goes back, through Alexander's deified head, to the head of Athena, and the symbol of Britannia derives ultimately from such state badges as the owl. In certain cities of Italy and Sicily, however, including Tarentum and Metapontum, a different technique was popular, the obverse type in relief being repeated intaglio on the reverse, very probably with the object of concealing the older types of coins imported for restriking. For a long time the early coins of Greece carried no inscriptions or, at most, with very rare exceptions, a letter or two referring to the issuing city or state authority.

Athenian relief types

Greek coin types, early and even later, were simple in conception and often taken from the animal world. They include many kinds of animals (with the bull, symbol of a river, very common); birds (such as the owl of Athens, the eagle of Zeus at Olympia, the dove at Sicyon); insects (like the bee of Ephesus); fabulous creatures (like the griffin at Abdera); and vegetable objects. Not uncommonly such types were chosen as punning allusions to a city's name—the lion at Leontini; the goat at Aegae; the quince at Melos; the sickle-shaped harbour at Zancle; the *selinon* leaf at Selinus; the cock, harbinger of *hemera,* the day, at Himera. In others a city's staple product was proclaimed, like silphium at Cyrene, a silver-miner's pick at Damastium, a bunch of grapes at Naxos, a wine jar at Chios. Cult associations frequently dictated the choice of type. Tarentum showed its mythical founder, the dolphin-rider Taras; Knossos, the Minotaur (half man, half bull) or Labyrinth; Croton, the tripod of Apollo; Poseidonia, a statue of Poseidon, god of the sea. Human or anthropomorphic figures, however, were comparatively rare on early Greek coins, though the famous gold darics, a name derived from Darius I, and silver shekels of Persia showed the great king in an attitude of attack. Much more popular was the representation of idealized heads of deities, which, once established for the two Athenas, Parthenos and Chalinitis, at Athens and Corinth, quickly became the vogue elsewhere, encouraged by the development of double-relief coinage (*i.e.,* coinage with obverse and reverse in relief), which allowed the head of a civic deity to be paired on the other side by the city's symbol. The Greek tyrants, as a rule, chose to respect the theory of coinage as the corporate expression of state economy and thus regarded coinage as too important a matter for private production. The traditions that, rightly or wrongly, associated all the great lawgivers—Pheidon, Solon, and Lycurgus—with the institution of coinage as well as with reform of weights emphasize its position as a fundamentally corporate right.

The Sicilian decadrachm

In Sicily the defeat of Carthage in 480 BC may have been commemorated by the famous decadrachms (*Demareteia*) associated with Queen Demarete, wife of King Gelon. These superb and now very rare examples of early classical genius showed on the obverse the head of Arethusa (the fountain nymph of Syracusan Ortygia), wreathed (possibly for victory), and on the reverse a chariot above a fleeing lion.

From the Persian Wars to Alexander the Great, 490–336 BC. For a century and a half the previous pattern of Greek coinage spread widely all over the Greek world, its quantity stimulated by a growing sense of nationalism, its intrinsic quality kept high by commercial competition, and its technique raised to new and often superb levels in an age of self-confidence. In the last half of the period the designing and engraving of coin dies (punches) reached a standard rarely to be surpassed. The head of a patron deity was now generally established as the obverse type and was often shown in very high relief, sometimes indeed facing, as a tour de force. Engravers, especially in Sicily and Italy, began to sign their dies, thus preserving the names of masters such as the Syracusans Euainetos, Cimon, and Eukleidas, otherwise unknown. Reverse types, now more complex, increasingly showed groups or genre scenes—*e.g.*, the splendid frontally squatting Silenus (foster father of the wine god Dionysus) on the coinage for the refounding of Sicilian Naxos in 461, Dionysus seated backward on a donkey at Mende, or the many mythological compositions on Cretan coins—often diminishing the previous importance of the city badge. Inscriptions, though still often contracted, were in general use. The principal coinage metal was silver, of which the Attic weight standard gradually conquered the Aeginetan. Electrum was continued in the east—at Cyzicus, Lampsacus, Mytilene, and Phocaea—traveling thence mainly to the Black Sea; in the west it was coined at Carthage. In both areas it was produced as an artificial alloy. Gold was continued in the darics of the Persian kings and in the fine later series of Lampsacene staters; it was also struck at Panticapaeum on the Black Sea and on occasion at Syracuse, Tarentum, and Cyrene. Toward the end of the period, Philip II of Macedon instituted what was to be a world-famous gold coinage, undercutting and ousting that of Persia. Bronze made its appearance late in the 5th century, replacing the minute silver obol and other fractional silver coins that had hitherto been used as small change.

The currencies of the period included a few that were of world importance. The silver of Corinth and its Adriatic colonies was very numerous and was abundantly accepted, outside the Corinthian territories, by Italy and Sicily. The electrum of Cyzicus bore types that deliberately recommended it to many markets. Persian gold and silver coins enjoyed immense popularity in the 5th century. Metapontum, Tarentum, Thurium, Velia, and Syracuse were among the more prolific silver mints of the west. But the most famous commercial currency of all was that of Athens, the silver tetradrachms of which were struck in large numbers, fine quality, and obstinately unchanged appearance. These coins traveled widely in trade and were imitated as far afield as Egypt, Arabia, and Persia.

Predominance of Athens. Economic expansion and naval hegemony gave Athens near-imperial control over its allies in the 5th century. It may have been as early as 449 that Athenian edicts forbade the striking of silver coins by the allies or the use of currency, weights, and measures other than the Athenian and provided that previously minted local currencies should be handed in for exchange against that of Athens. The subjection of Aegina to Athens from 456 and the cessation of its famous and long-competitive "turtles" facilitated the monetary dominance of the "owls," which was carried further, stage by stage, as Athenian "allies" revolted, were reconquered, and lost their independence. But the embargo put by Athens on local silver coinage was not absolute and perhaps was not expected to be. Major allies such as Samos, Chios, and Lesbos continued their own currencies; Phocaea, Mytilene, and Cyzicus, though ceasing to coin in silver, continued with electrum. In other cities, small change in silver was issued. Beyond the effective range of Athenian power, cities in Pamphylia (*e.g.*, Aspendus) and in Thrace (*e.g.*, Abdera and Aenus) could continue silver coinage on a non-Attic standard, and the failure of Athenian control is seen in the sudden and often beautiful coinages of cities that threw aside its dominance, such as Olynthus from *c.* 430, or in the changed weight standard of others (*e.g.*, Acanthus). During the Peloponnesian War, Sparta cut off the supply of silver from the Laurium mines, and by 407 Athens was melting the gold Nikai (victory statues) from the Parthenon to make emergency coins, followed the next year by bronze small change—an unpopular substitute for the tiny silver coins previously carried in the mouth. City after city now rebelled against Athens, and there was a sudden burst of independent coinage.

Athenian coinage revived, with unchanged types, after the Athenian admiral Conon's successes against the Spartan fleet in 394. But wary former allies formed defensive leagues, as shown by current coinage, with a type of the Greek hero Heracles and the inscription ΣΥΝ ("the alliance"), by Cnidus, Ephesus, Samos, Byzantium, and other cities under Rhodian leadership. Rhodes spread its own coinage (with its head of the sun-god Helios and punning badge of a rose—Rhodon) widely in the eastern Mediterranean. Phocaea and Mytilene established a monetary union for their electrum. From 404 the Aeginetans were coining again, and on their former weight standard, though with a tortoise replacing the turtle. Corinthian coins continued to pour out. In the north a variety of important mints opened, and coins from mints in Asia Minor, notably Cnidus and Ephesus, testify to the prosperity brought by autonomy.

Monetary unions

Artistic development. In contrast to the deliberate archaism of Athenian types, a wide flowering was seen elsewhere. Sometimes this was the result of hybridizing influence, as when Greek artists rendered Scythian motifs at Panticapaeum or Punic ones for Carthage and such of its Sicilian colonies as Segesta and Eryx. Sometimes an artistic tradition was regional, harsh, and arresting, as in Crete or, as in Massilia and Emporion in the far west, a weak reflection of finer styles. Generally, however, there was an internationally high standard in coin design. Elis, guardian of the temple of Olympian Zeus and famous for its quadrennial Olympic Games, no doubt attempted to impress visitors with its superb coinage. On the coins issued from *c.* 500 to 322 the thunderbolt and eagle of Zeus were shown with Victory in various attitudes; later the heads of Zeus and Hera were nobly represented. In northern Greece brilliant artistry characterized the coins of Amphipolis, Acanthus, and Chalcidian Olynthus. The coins of Clazomenae and Cnidus in eastern Greece were also notable for their designs.

It was in Italy and Sicily that the finest work appeared. In Italy, Tarentine silver continued its type of Taras on a dolphin. In the middle of the 5th century the agonistic type showing a horseman appeared; the celebrated Tarentine cavalry was thus commemorated down to the middle of the 4th century. About 340 Tarentum issued very beautiful gold coins with a head of Persephone and, on the reverse, the infant Taras appealing to Zeus enthroned. Heraclea, founded in the middle of the 5th century, issued fine staters with a helmeted Athena and Heracles seated or strangling or wrestling with a lion. Metapontum introduced a most striking head of its founder, Leucippus. Other mints of the time were at Neapolis, with its types of the siren Parthenope and her father, the man-headed bull Achelous; at Velia, with its head of a nymph and, on the reverse, the eastern type of a lion attacking a bull; at Thurium, with its unusually fine head of Athena and the powerful bull on the reverse; and at Terina, remarkable for its beautiful treatment of the Victory type.

In Sicily, and particularly in Syracuse, the engraver's art reached perfection. The coins of Syracuse showed many varieties of the heads of Arethusa and Persephone, and the chariot of the reverse was found capable of varied treatment. After the middle of the 5th century, artists began to sign their work, and it is thus possible to prove that other towns engaged engravers from Syracuse. The Syracusan coinage was mainly silver. During the siege by the Athenians, beautiful little gold coins were struck with,

Zenith of Syracusan coinage

reverse, Heracles strangling a lion. With the prosperity following the enemy's defeat, Syracusan art reached its zenith. As the Demareteion commemorated the defeat of the Carthaginians, so the great series of decadrachms perpetuated the memory of the victory of 413 over the Athenians. The agonistic types and the word *athla* on some of them show that they were distributed at the games held to celebrate the victory; their types were widely copied, and their engravers, Cimon and Euainetos, gained a place among the world's greatest artists.

Among other cities of Sicily there was a notable series from Acragas in the 5th century, with its beautiful double-eagle type, seen most magnificently on the rare and famous decadrachms. Camarina showed fine types of the river god Hipparis and the nymph Camarina on a swan. Himera, before its destruction in 409, issued some very interesting types, such as the nymph Himera sacrificing while Silenus beside her bathes at the thermal spring for which Himera was noted; or Pelops (a grandson of Zeus) in his chariot, referring to a victory of a Himeran at the Olympic Games, which Pelops is said to have founded. Catana used the artist Heracleidas to design a splendid facing head of Apollo. Selinus abandoned its parsley leaf and issued some remarkable types, notably that of Apollo and Artemis in their quadriga and, on the reverse, the local hero sacrificing at an altar, alluding to the cessation of the plague as a result of appeals to Apollo as healer.

Silver tetradrachm from Syracuse, Italy, signed by the engraver Cimon above the headband of the nymph Arethusa, *c.* 410 BC. In the British Museum. Diameter 28 mm.

From Alexander the Great to the end of the Roman Republic, c. 336–31 BC. Alexander introduced a new era in coinage, struck in vast quantities at a variety of mints from Macedonia to Babylon with uniform types and weights. After his death in 323 BC the Diadochi ("Successors"—a reference to the chief officers who partitioned his empire) were to reflect the importance of his coinage in their own differentiated issues—Seleucus in Syria, Philip Arrhidaeus in Macedonia, Lysimachus in Thrace, and Ptolemy in Egypt, where, except for tentative gold coined by Tachos and Nectanebo II between 361 and 343, no coinage had previously been struck. Alexander's influence on the Greek fringe was no less marked. The Arsacid kings of Parthia instituted a Greek style of coinage, as did Bactrian kings, culminating in the splendid portrait decadrachms of Amyntas *c.* 150 BC, while, even farther to the southeast, Indo-Greek kings struck coins, inscribed in both Greek and Prākrit, to the end of the 2nd century. The flood of coins of Philip II and Alexander, penetrating Europe from the Balkans, resulted in progressive imitations by Celtic peoples westward along the Danube until these imitations themselves influenced coins in Gaul and Britain in the 1st century BC. In the Mediterranean west, by contrast, Greek coinage yielded to the steady advance of Roman power; the late issues of Spain and Mauretania were of hybrid Greco-Roman origin.

The coin portrait. The coinage of Alexander established a new style: the coin portrait became an almost regular feature in Greek currency that was predominantly regal. The portrait, however, was not at first that of a living monarch. Philip II and Alexander were content with their names on their coins, of which the obverses showed, for Philip, Apollo and Zeus and, for Alexander, Heracles and Athena. Alexander added the title basileus (king) only after

Alexander the Great as Zeus Ammon on a silver tetradrachm of Lysimachus, 297–281 BC; thought to be a copy of a portrait by Lysippus. In the British Museum. Diameter 30 mm.

his Persian conquest. After his death his deified portrait appeared on the coins of Lysimachus in Thrace and on the early coins of Ptolemy I in Egypt. It was not until 306 that a living king put his own portrait on his coins, when Ptolemy I appeared, still as god, with the aegis of Zeus. Seleucus I similarly put himself on his coins as Dionysus; in time the divine attribute was dropped, and the ruler appeared as a mortal wearing only the royal diadem. In Macedonia, Arrhidaeus, Cassander, and Antigonus still followed the types of Alexander; and the early coins of Demetrius I Poliorcetes (336–283) were without a portrait. Soon, however, his own portrait appeared, still with the horns that deify him. His successor had only types of deities. Pyrrhus did not appear on any of his extensive coinages, but the last two kings of Macedonia, Perseus and Philip V, left very fine portraits. The kings of Pontus, notably Mithradates VI, had a magnificent series of portraits. The kings of Pergamum used the same portrait throughout, that of the founder of the dynasty, Philetairus I, and the Ptolemies in Egypt throughout their long series used only the head and legend of Ptolemy I, except on certain special issues. Among the early Seleucids, Antiochus I was reluctant to drop the portrait of Seleucus I, but the portrait of the reigning monarch became the rule.

After the vast issues of gold by Philip II, Alexander (under whom its price in relation to silver cheapened to 1:10 from 1:13 or more), and Lysimachus, gold was but rarely struck. Silver was the general metal of coinage; the Attic standard, which Alexander had adopted for his tetradrachms, became the monetary standard of the Western world, and there was a great increase in the bronze coinage. Egypt, however, kept to its own standards and to gold.

The Attic standard

As the greater part of the Greek world was now ruled by the Diadochi, their various coinages naturally formed the main currencies of commerce. Third-century Athenian coinages were scarce except in bronze. In 229, however, Macedonia lost its supremacy over Athens, and friendly relations were established between Athens and Rome. Shortly after 200 the abundant issue of tetradrachms of the "new style" began, which went on for slightly more than a century, replacing the "archaic" Athena with a copy of the head of the Parthenos of the Athenian sculptor Phidias, and with an owl on the reverse perched on a Panathenaic amphora. Corinth went on striking its stater until 229, when, with its surrender to Antigonus III Doson, king of Macedonia from 227, the long series came to an end.

Rise of Rome. After the Roman conquest of Greece it is clear from the resumed activity of the mints that the Greek cities were autonomous in one respect at least, for the silver coinage required in Greek territory could be supplied only by Greek mints, the task being beyond the power of Rome at this time. The Thessalians issued silver coins of the type of Zeus and Athena and the legend *Thessalon;* a similar coinage was issued by the Boeotians. Maronea and Thasos issued tetradrachms that became a great commercial currency for trade across the Danube with the Scythians and Celts who imitated them. Macedonia itself issued tetradrachms bearing the names of Roman governors. In Asia, after the defeat of Antiochus III at Magnesia, there was an outburst of tetradrachms of Attic weight and local types at towns such as Lampsacus,

Smyrna, and Magnesia. Other cities resumed the issue of Alexander tetradrachms, continuing to the middle of the 2nd century, when the Roman province of Asia was set up and cistophori replaced them. These, so called from the Dionysian chest (the sacred box or basket carried in the worship of Dionysus, usually shown containing snakes), which formed the principal type, were first struck at Pergamum after 228 BC; the reverse is a bow in a case between two serpents.

Coinage of Etruria

In the west the rise of Rome in the 3rd century introduced a new factor into the history of Greek coinage. The first coinage to disappear was that of Etruria—a silver issue curiously always left blank on one side—after a life of two centuries. Rome's early intercourse with the Greek cities of Italy is reflected in the Romano-Campanian coinage. In the south the Italian campaign of Pyrrhus left its mark on various coinages, notably at Tarentum. The towns of Magna Graecia gradually lost their silver coinage under Roman influence, although Greek bronze coins lasted until the 1st century at Paestum.

In Sicily in the 3rd century, derivatives of earlier Syracusan coinage began to dominate the whole island. The Punic Wars brought the Romans to Sicily, where the Carthaginians had been established since the end of the 5th century and had struck coins of Syracusan and other Sicilian types with Punic legends and later with their own types. Sicily became a Roman province; henceforth, only bronze was struck in it, and these local coins continued into the first century, when the last trace of Greek coinage in the west disappeared.

Subsidiary Greek silver coinages under the Roman Empire. Although Greek coins under the Roman Empire were nearly all of bronze and intended for local circulation, exceptional coinages in silver were allowed by Rome as a continuation, for wider regional use, of important preconquest currencies. The largest of these, running from Augustus to Diocletian's coinage reform, was minted at Alexandria to supply the needs of Egypt and was generally of billon (an alloy of silver and base metals). Inscriptions were in Greek and obverses bore the emperor's portrait, while reverses (dated in regnal years by Greek numerals) showed a wide variety of types embracing Hellenistic, Roman, and Egyptian symbolism.

Alexandrian coinages

In Syria silver tetradrachms continued to be struck, mainly at Antioch but also at Tyre and some other mints. These gradually became baser in the course of the early 3rd century. Bronze was also struck by the Romans at these mints and frequently bears the letters *S C* (*Senatus consulto*), showing, like similar issues at Rome, imperial initiative exerted through senatorial agency. Of several other local silver coinages the large series of drachmas struck at Caesarea in Cappadocia from Tiberius to Commodus is the most important. The most usual type was a local one of Mount Argaeus.

A number of vassal states and protectorates continued to issue their own coinages in the precious metals until they became Roman provinces. The only gold coinage of this kind is that of the kings of the Bosporus, who struck coins from the time of Augustus to the beginning of the 4th century. This coinage became gradually debased. In Africa the kings of Mauretania issued their own gold and silver until AD 40.

Coinage in Judaea. Another pre-imperial series continued under the Roman Empire was that of Judaea. Except for rare silver coins of much earlier date, with types of Greek origin but marked with brief Hebrew inscriptions, there were no Judaean issues until *c.* 135 BC; the Seleucid coinage of Syria had in the meantime supplied the necessary currency. Antiochus VII, however, had granted to the Hasmonean high priest Simon Maccabeus the right of coinage, which enabled the natural resistance of the Maccabees to Greek polytheism to be satisfied by the representation of specifically Jewish symbols. These coins, like those of the rest of the dynasty, were of copper. Alexander Jannaeus (103–76 BC) was the first of the Maccabean priestly princes to style himself king on his coins, which bore his name and title in Greek as well as Hebrew, but Pompey's withdrawal of the kingly title was reflected in the coins of John Hyrcanus II. Antigonus Mattathias (40–37 BC), the last of the Maccabees, introduced the seven-branched candlestick as a type. Under the Herodian dynasty, from 37 BC, Greek alone was found on Judaean coins. Herod Philip (4 BC–AD 34) gravely infringed Jewish convention by showing the effigy of the Roman emperor; Herod Agrippa I (41–44) was more adroit, avoiding the imperial portrait in Judaea but introducing his own in Caesarea.

Coinages of Jewish revolt

From AD 66, silver shekels and halves were coined, with some bronze, at "Jerusalem the Holy" to mark the first revolt against Rome: issues of year 5 (AD 70–71), a precarious one for the insurgents, are very rare. After the Flavian conquest, there were no further Jewish coins until the second revolt (132–135), under Bar Kokhba, when silver and bronze briefly proclaimed "the redemption of Israel and the freedom of Jerusalem." Jewish coinage ceased with the revolt's collapse.

Greco-Roman bronze

Greek bronze imperial coinage, to AD 268. Under the Roman Republic many Greek cities and districts continued to issue their own bronze coins, and, particularly in Asia, these local Greek coinages went on under the empire down to Gallienus.

The right of coinage in Greece was sometimes continuous and sometimes intermittently permitted by the emperor or governor. Coins were struck not only by single towns but also jointly by alliances of towns (*homonoiai*). The general type is everywhere the same: obverse, a bust and, reverse, a type of local interest. Under the republic the Greek cities usually placed on the obverses of their coins an allegorical bust of some local hero, the local city goddess, or a personification of the people, the municipal council, or the senate. The Tyche, the titular goddess of the city, appears as a female bust wearing a mural crown. The goddess Roma is found as a helmeted female; *e.g.*, at Smyrna. Under the empire the usual obverse type is the head of the emperor, as on the imperial series proper. There are some notable exceptions. Macedonia, for example, had the head of Alexander the Great. Athens was privileged by Hadrian to use the head of Athena in place of the emperor's.

Representations of statues

It is the reverse types of this series of coins that give them their importance. The coins of Athens preserve representations of many statues famous in antiquity that have long since perished, such as the Athena Parthenos of Phidias; the great Athena Promachos on the Acropolis, visible far out at sea; or the Dionysus of Alcamenes, possibly a pupil of Phidias. A coin of Elis preserves the Olympian Zeus of Phidias, and one of Lacedaemon the Apollo of Amyclae, near Sparta. Local cults and incidents in the lives of the Greek divinities are common types. Local celebrities are also recorded, for example, Homer at several of the various towns that claimed him as a native (notably Smyrna), Anacreon at Teos, Sappho at Eresus in Lesbos, Herodotus at Halicarnassus, and Alcaeus at Mytilene, which recorded on its coins a whole series of its famous men, most otherwise unknown. Reverse types also represent many architectural views of great importance, and the celebration of games and festivals is frequently recorded on coins.

In conclusion, mention may be made of a notable example of the preservation of a local tradition on a Greek imperial coin. On a coin of Septimius at Apameia in Phrygia there appear as reverse type a man and woman in a chest or ark floating on water, with a raven on the top and a dove flying above with a branch in its beak; to remove any doubt about the scene represented, the ark is labeled NΩ (NO; Noah), and the coin is evidence of the local tradition that the ark rested on the mountain behind Apameia.

ROMAN COINS, REPUBLIC AND EMPIRE

The beginnings. Although Roman coinage soon diverged from Greek conventions, its origins were similar. Rome, founded in the 8th century BC, had no true coinage until the 3rd. Roman historians later attributed coinage unhesitatingly to the much earlier regal period: some derived *nummus* ("coin") from Numa Pompilius, by tradition Rome's second king, and Servius Tullius was credited with silver coinage, as well as with bronze stamped with the device of cattle. Roman historical tradition, however,

seriously confused the elements of the true picture. Rough, unworked lumps of bronze (aes rude) were certainly used as a metal currency from the 6th century, if not much earlier, perhaps in rare conjunction with very small quantities of unworked gold and silver, themselves also passing by weight. Simultaneously, standards of value appear to have been expressed in terms of cattle and sheep, as is clear not only from the derivation of *pecunia* ("money") from *pecus* ("cattle," or "sheep") but also from the early assessment of fines in oxen and sheep. From this it was falsely concluded that bronze coins marked with the device of cattle existed from the 6th century. In fact, the expression of values in terms of cattle may have lasted, officially, into the 5th century, for it was not until the decemvirs (a legislative commission) codified the law and drew up the Twelve Tables (451–449 BC) that fines were fixed in bronze. This bronze still consisted of unworked lumps or, at most, rough bars of irregular weight.

During the 4th century BC, Roman contact with the Greek cities of southern Italy slowly increased; these included such prolific mint cities as Nola, Hyria, and Naples. The coinages of these cities consisted of silver didrachms, of which Rome presumably made use in any necessary dealings with them. A hint is given, however, of widening Roman monetary interests by two issues of bronze token coinage. These, though certainly not produced at Rome, may perhaps be regarded as the earliest coins in the name of the Romans, struck at Naples *c.* 325–285 within the terms of their alliance and intended for use in Campania, as distinct from Rome and Latium. It is unlikely, indeed, that a mint in the proper sense existed at Rome before 289, the year to which Pomponius assigned the establishment of *tresviri* (a board of three officials) who should be *aeris flatores* ("bronze melters"); and this mint (in the temple of Juno Moneta) did not yet produce true coins but aes signatum, bronze bars (of about six pounds) lacking a mark of value but bearing on each side a clearly recognizable type (including cattle) and perhaps equivalent in value to a Greek silver didrachm.

Bronze token coinage

These aes signatum bars were halfway between aes rude and true coinage. In 269 true coinage appeared. It consisted of aes grave, large circular cast coins of bronze all bearing marks of value, from the as (weighing one pound) down to its 12th, the uncia; the obverses showed the head of a deity, the reverses a ship's prow. These were paralleled at mints elsewhere by similar cast coins; their types showed not, as at Rome, Latin deities but rather Greek (in the south) or Umbrian and Oscan. At the same time, there appeared struck silver didrachms, on the standard of the Greek silver coins of Campania, bearing Greek types but marked *ROMANO* or *ROMA*. Accompanied by small struck bronze token coins, these were issued from Campanian mints, and they probably continued to the Second Punic War, terminating in a new issue of silver coins of Roman style and types (marked *ROMA*), including Jupiter in a quadriga (four-horse chariot) from which their name, quadrigati, derived; they were imitated in electrum by the Carthaginians in Capua. The quadrigati were of the weight of the lighter Romano-Campanian didrachms and reflected the rising cost of silver at a time of stress; concurrently the cast bronze coinage of Rome dropped steadily in weight from an as of one pound to one of three ounces or less. Financial stress is similarly to be seen in the exceptional issue of gold units and halves. Toward the end of the Second Punic War the quadrigati were replaced by silver coins of half their weight, with a Victory on the reverse, and hence called victoriates. By *c.* 190 a mainly silver coinage, Latin-inscribed, was in production at Rome and other authorized mints, accompanied by bronze coinage so greatly reduced in standard (and thus size) that it could at last be struck instead of being cast.

Introduction of the denarius. Adjustment of the previously fluctuating relationship between bronze and silver was first secured by the issue *c.* 211 BC of the silver denarius (marked *X—i.e.,* 10 bronze asses), together with fractional coins, also of silver (marked *V—i.e.,* five; and *IIS—i.e.,* 2½ asses—a sesterce, or sestertius). The denarii were lighter than the quadrigati; their types were a Roma head on the obverse, with the Dioscuri (the twin deities Castor and Pollux) and *ROMA* on the reverse. Their production came to be confined principally to the mint of Rome. The victoriates, again lighter (their weight standard had come from Illyria), were issued until *c.* 150 BC, being perhaps intended for principal circulation outside Italy. The denarius, however, quickly established itself as the major currency in the central and western Mediterranean. In its eastward expansion, Rome learned to make use of local currencies—gold staters of Macedonia and silver tetradrachms of Athens or Asia. Rome was also prepared to employ Macedonian gold in the west, as was shown by the release to western markets of large quantities of gold staters after *c.* 150 BC. In the 2nd century BC, Roman coinage in gold was exceptional. Coinage in bronze, however, continued, but further variation in silver–bronze values was seen in two developments. The as dropped in weight to that of an uncia and then less, becoming a token currency; together with its fractions, it was now always struck and not cast. The value of the denarius in terms of bronze was altered, being revalued *c.* 133 at 16 instead of 10 asses; the silver quinarius (now of eight asses and with the types of the victoriate) became rare; and the silver sesterce (now equal to four asses) virtually disappeared. After *c.* 80 BC the striking of bronze was discontinued until the time of Caesar.

Employment of local currencies

These developments mirrored the economic difficulties of the day. Reduction of the weight of the as from one to ½ ounce in 89 BC was accompanied temporarily by debasement of the denarius, resulting in the issue of denarii with serrated edges, intended to show that they were not plated.

Control and content of the coinage. The coinage was controlled by the Senate, acting for the sovereign people; and the conduct of the mints was in the hands of boards of junior magistrates, the *tresviri.* From about the mid-2nd century, each of a mint's three *tresviri* normally issued coins bearing his own name, and on special occasions these were supplemented by issues of quaestors, curule aediles, prefects, or praetors; these were distinguished by special inscriptions such as *ex s(enatus) c(onsulto)* and *ex a(rgento) p(ublico).* The function of all these officials was quantity and quality control.

The moneyers' names at first were shown as simple monograms. The Dioscuri reverse was followed by Diana or Victory in a biga (two-horse chariot), and these again by figures of Jupiter, Juno, or Apollo in a quadriga, with the moneyers' names in fuller form. In the mid-2nd century BC, however, newer tendencies appeared, as when Sextus Pompeius Fostlus paired the Roma obverse with a reverse showing his traditional ancestor Faustulus discovering the wolf and twins; the reference was to the greatness of Rome, but it was to be seen through the lineage of a moneyer. Later republican denarii gave keen expression to party politics, as when corn ears recorded *c.* 100 the purchase of grain by the quaestors Piso and Caepio, or the head of Ceres with ploughing oxen proclaimed the program of the Marians, or Sextus Nonius Sufenas advertised the games that he had staged as praetor.

It was in the provinces, however, that the republican coinage took the decisive steps toward its finally imperial character. Campaigning generals began, in the 1st century BC, to operate mints for paying their troops in the field. In Italy mint policy had usually looked beyond personal politics to the state. But the military coinages of the *imperatores* equated the state with the personalities of the generals. Such were the aurei and denarii struck from eastern mints *c.* 82–81 by Sulla, with, obverse, *L. SVLLA* and head of Venus (his family patroness) and, reverse, *IMPER(ator) ITERVM,* priestly jug between trophies. Pompey issued comparable aurei *c.* 61 (also in the east). From these precedents the earlier coinage of Julius Caesar followed naturally in the late 50s and early 40s, with, obverse, *CAESAR* and elephant (the family badge) and, reverse, priestly symbols, or obverse, head of Venus (his traditional ancestress) and, reverse, *CAESAR,* Gaulish trophy, and captives. Such coinages still avoided the portraiture of a living man, the only examples of which hitherto had been on provincially struck coins.

Steps toward imperial coinage

Caesar and after. In the last year of his life, Caesar developed personal control of the coinage to a point at

which it lay ready to hand for Augustus to use later as a fully imperial instrument. Already, from 46 BC, coinage in gold had been instituted in Rome by Caesar's lieutenant Hirtius. Caesar's seizure of the treasury and his expansion of the annual board of moneyers from three to four members indicated his intention to deal absolutely with the coinage. In 44, denarii were issued in considerable quantity by his *quattuorviri,* bearing the portrait of Caesar on the obverse, with such inscriptions as *DICT(ator) QVART(um)* or *DICT(ator) PERPETVO,* and Venus Victrix or other semipersonal reverse types. For the token coinage a new alloy was now first struck—yellow orichalcum or brass, a copper–zinc alloy. Caesar may have enjoyed a monopoly of zinc from mines in Cisalpine Gaul.

From 44 to 31, bronze coinages were struck at various non-Italian mints, notably in or around Sicily, by officials attached to the cause of one or other of the members of the second triumvirate—Antony, Octavian, and Lepidus. But the principal issues of these years were of gold and silver. The mint of Rome continued its regular series until *c.* 37 and then ceased. Antony's coinage emanated at first from Gaul, then increasingly from eastern mints, including his cistophori and denarii (some showing his head conjoined with Cleopatra's) struck in Asia: his vast issue of often base denarii showing warships and military standards, shortly before the naval battle of Actium, was eastern. Octavian coined mainly in Gaul, Italy, and Africa. The piratical movement of Sextus Pompeius was reflected in the activity of a mint or mints in Sicily.

It was characteristic of most of the gold and silver after 44 that it showed portraits of the rival statesmen on the obverses, with reverses that alluded to their achievements or policies. This was true even of the "liberators" who murdered Caesar, for a famous eastern issue in the name of Brutus showed his portrait, with *BRVT(us) IMP(erator)* on the obverse, with reverse *EID(ibus) MAR(tiis)*—the fatal Ides of March—and daggers flanking a cap of liberty. By the close of the Roman Republic, three factors had entirely transformed the originally simple idiom of the early denarial coinage: gold was freely struck in addition to silver; the types of both were personal to military leaders and included living portraiture; and coinage could be produced elsewhere than at Rome.

Early imperial mint policy. Augustus (27 BC–AD 14) based the coinage on the aureus of $^1/_{42}$ of a pound of gold, equivalent to 25 denarii, each of $^1/_{84}$ of a pound of silver, the metals being struck almost pure. The denarius was valued at 16 asses. Token coinage consisted henceforth of brass sesterces and dupondii (equal to four and two asses, respectively), with copper asses, halves, and quarters, the as being the most common. Nero in AD 64 lightened aureus and denarius to $^1/_{45}$ and $^1/_{96}$, respectively, but debasement of silver subsequently took place. Under Septimius Severus it reached 40 percent, and Caracalla issued a debased double denarius of the weight of only $1^1/_2$ denarii. Gallienus' double denarius of copper and silver, leached to give a more silver-rich surface, marked a monetary breakdown, only partially cured when Diocletian and Constantine again made gold the firm basis for supplementary pure silver and abundant copper coinage.

Early imperial mints

Augustus' earliest gold and silver were coined chiefly in the east—*e.g.,* at Ephesus and Pergamum—and more briefly at Emerita in Spain. Bronze also was mainly eastern, though some was struck at Nemausus (Nîmes). The Rome mint was reopened *c.* 20 BC for gold and silver and remained open for this purpose until *c.* 12 BC; its bronze continued irregularly. From 12 BC, Lugdunum (Lyon), with other mints of uncertain identity, undertook the main western coinages in gold, silver, and bronze. After 64 Rome was once more the chief mint for all metals. Official mintages were supplemented by a mass of regional or local coinages, while official coinages from eastern mints provided necessary currency for local Roman frontier forces.

The bronze of Rome was marked *S(enatus) C(onsulto)* and continued to bear the names of the *tresviri monetales*—masters of the mint, now reduced to their traditional number—until 4 BC. But *S C* also appeared on bronze from Lyon and Antioch in imperial provinces, showing that whatever nominal senatorial rights of coinage still lingered on—the *tresviri* are known until the 3rd century—the emperor wielded effective control over all metals everywhere. This was logical, since his economic powers were equally comprehensive. In fact, the old senatorial mint was transferred from the temple of Juno Moneta on Rome's Capitoline Hill and merged, probably after the fire of 64, with an imperial mint for gold and silver elsewhere in the capital. Henceforth, it worked in sections—six were normal later—controlled immediately by an imperial procurator and staffed by slaves or freedmen.

Portrait of Nero on a bronze sestertius struck at the mint in Lyon, Fr., *c.* AD 64–66. In the British Museum. Diameter 36 mm.

Portraits and types. The use of Caesar's own portrait upon coinage set a precedent; although under Augustus and Tiberius token denominations occasionally lacked the imperial portrait, it was thereafter an essential element of virtually every gold, silver, and bronze coin of the official mints, as also of nearly all provincial and local coins. Emphasis on the personality of the emperor (extended sometimes to empresses, sons, or deceased members of the imperial house) was a powerful propaganda instrument in a coinage that circulated throughout a vast empire. The great series of imperial portraits, from Augustus to Romulus in AD 476, is artistically outstanding. Many of the finest appeared on the large brass sesterces down to the 3rd century and on the even larger bronze medallions produced for presentation; but particular care was taken over the portraits for gold, which, being softer, showed a beautiful and highly sensitive impression. Nothing is known of the portrait artists, though it is likely that they were often from the Greek East.

Imperial reverse types

Imperial reverse types, if artistically less remarkable, are uniquely important for the unparalleled fullness of the historical commentary that they supply. The major mints provided annual evidence of imperial interests: victories in war; frontier defense (*e.g., Rex Parthis datus*—"A king is given to the Parthians"—of Trajan); a well-earned peace (*e.g.,* the *Pace terra marique parta Ianum clusit*—"There being peace on land and sea, the doors of the Temple of Janus were closed"—of Nero); the birth of an heir or alternative provision for the succession; public shows; acts of social reform or public relief (*e.g., Civitatibus Asiae restitutis*—"For the restitution of the citizenries of Asia"); imperial journeys (*e.g., Adventus Augusti*—"The arrival of the emperor"); and religious or other anniversaries (*e.g.,* the *Felix temporum reparatio*—"Happy days are here again"—on Rome's 1,100th birthday). Their interpretation demands care, since, being selected by imperial officials, their tenor can conflict with the attitude of anti-imperial historians. But they show the efforts made by emperors, as the omnipotent semireligious heads of a huge and heterogeneous empire, to conciliate and inform. They contributed powerfully to the growing conception of an eternal Roman empire, seen no less in the special types of eagle (the soul flown heavenward) or funeral pyre or temple in honour of "good" emperors consecrated as *divi* than in the annual record of military victory, economic security, and provincial peace and implicit in the regularity of imperial succession. The normal colour given to this imperial program was religious, for the coinage types commonly embraced such characteristically Roman concepts as Aequitas (Justice), Fides (Faith), and Concor-

dia (Harmony)—social virtues operating in the guise of minor deities.

The 4th century and after. Diocletian's institution of the tetrarchy, by which the empire was divided administratively between two Augusti and two Caesars, brought fundamental changes in social and economic policy; the instability of prices called for complete renewal of the monetary system. His coinage reforms took place in stages from *c.* 286 to *c.* 296. First, new aurei were struck at 60 to the pound of gold. Then, *c.* 293–294, new silver coins, of good purity, were struck at the revised Neronian weight of 96 to the pound of silver. Finally, *c.* 294–296, new copper coins appeared that were larger and intrinsically more valuable than the small debased double denarii of previous reigns. The contemporary names of these silver and copper pieces are not known. This reformed coinage was struck at a variety of mints from Londinium (London) to Alexandria, most of which coined in all three metals. Types were closely controlled in the silver and copper coinage; in the latter the almost universal type was for some years that of the "Genius Populi Romani." The obverse bore the portrait of one or other of the tetrarchs, each of whom coined with portraits of all four.

The breakdown of the tetrarchy after 306 weakened the new system. Copper was quickly and steadily lightened, and silver struck very sparingly. Gold, however, continued in good supply; and though Constantine's solidus showed a reduced weight standard, there was no shortage of gold throughout the rest of the 4th century. In time, silver coinage increased, especially after *c.* 350, when the miliarense (1/1,000 of a gold pound) and smaller denominations appeared. By the end of the 4th century, however, the size of copper coins had dropped very sharply, and in the 5th, until the Western Empire collapsed in AD 476, the western coinage consisted finally of gold with a little silver, struck mainly from the mints of Ravenna and Rome.

Coinage under Constantine

From 312, when Constantine became emperor of the West, coin types began to show new tendencies. The imperial portrait was still the dominant feature. Reverses displayed complementary themes—the glory of the army, vows for continued imperial rule, the constant struggle against barbarian pressure on the frontiers. The old variety of pagan gods—Jupiter excepted—mainly disappeared, though Sol, popular from Aurelian onward, was used, especially by Constantine. Christian emblems did little to take their place, though the Christian monogram, the Greek letters chi and rho superimposed, sometimes on a standard, began to appear with Constantine and was combined with the alpha and omega under Constantius II and Magnentius. On the whole, however, there was an unavowed truce between Christianity and paganism, only occasionally broken, as when Julian revived a range of pagan types; the full development of the Christian tradition in coinage was reserved for Byzantium.

COINAGE IN WESTERN CONTINENTAL EUROPE, AFRICA, AND THE BYZANTINE EMPIRE (5TH–10TH CENTURY)

The fall of Roman power in the West left the gold currency of the Byzantine Empire undisturbed; it was to become the most dominant single influence in European coinage for 1,000 years, competing at first with the gold of the Arab caliphates and later with that of the great Italian commercial republics as well. Byzantine coinage, in its continuity, contrasted strongly with the often erratic monetary systems from the 5th to the 7th century in western Europe, where Germanic invaders inherited the apparatus, money included, of the Roman Empire. In general, they took over the main features of late Roman coinage. Emphasis on gold continued, with silver and some bronze; gold chiefly served for the triens, or third (1/3 of the Constantinian solidus). The types of the gold coins for some time reflected Byzantine prestige, showing a formalized portrait obverse and titles of the reigning Byzantine emperor, toward whom widespread respect was paid even when Western kings began to add their personal monograms to the normal Victory reverses. Imperial prerogative, so powerful an influence on western gold, had less effect on silver, the types of which in the West became more flexible; in bronze, where obvious efforts were at times made to link with traditional Roman design, flexibility was greater still. In technique these coinages varied widely: that of Italy was not without elegance; that of Spain developed an elaborately stylized balance, depending largely on its bold letter forms; the highly abstracted figures of Gallic coins have found great favour among 20th-century artists, while those of Africa and Britain were in general considered artistically inferior. The weights of gold coinages were kept at a reasonably steady level, though fineness ultimately declined with the economic decline of the issuing kingdoms themselves.

Post-Roman coinage in the West. In Italy Odoacer (476–493) had coined in silver and bronze at Ravenna after setting up a Teutonic kingdom. The Ostrogothic coinage that followed, from Theodoric (493–526) onward, consisted of gold, mainly imitating current Byzantine issues and with the imperial portrait (Theodoric's fine portrait on a unique triple solidus is wholly exceptional). Silver and bronze were supplementary. The Lombards of Italy (568–774) had no distinctive coinage of their own until the gold struck in the name of Grimoald, duke of Beneventum (662–671), which was followed by gold and silver from a number of mints elsewhere. In Africa the Vandal kings Gunthamund (484–496) and Hilderic (523–?530) issued silver and bronze coinage, respectively, inscribed with their names; the types and denominations looked to imperial models and, in the case of the bronze, to those of Carthage especially. Vandal gold was perhaps struck by Gaiseric (428–477) or Huneric (477–484) in the Byzantine emperor's name, but in the absence of any royal monogram it cannot easily be attributed. The chief Spanish coinage was that of the Visigoths, who controlled southern Gaul also and—after Leovigild (568–586)—Suevia (modern Galicia), with its rich gold mines; hence the fact that of 79 Visigothic mints a high proportion was concentrated in northwestern Spain. Visigothic gold coinage was produced up to the Arab invasion in the 8th century and consisted almost entirely of thirds, at first imitating Byzantine models, and bearing kings' names and titles. The most prolific mints were Mérida, Toledo, Seville, Tarragona, and Córdoba.

Ostrogothic coinage

Gold triple solidus of Theodoric from the mint at Rome, *c.* AD 500. In the Bibliothèque Nationale, Paris. Diameter 34 mm.

By courtesy of the Bibliotheque Nationale, Paris

In Gaul the Burgundians struck their own imitative gold thirds, first, under Gundobad (473–516), inscribed with a royal monogram, though not yet displacing the imperial name and portrait. The largest of the Gaulish coinages, however, was that of the Merovingian Franks, beginning with Clovis I (481–511). The gold consisted mainly of thirds, at first with some subsidiary silver and copper, inscribed by Theodoric I (511–533/534) and Childebert I of Paris (511–558) with their own names. As elsewhere, the types of the gold borrowed steadily from the imperial series, either the former Roman or the current Byzantine. Reverses showed a Victory, though the theme of the "cross on steps" of Tiberius II (578–582) gradually displaced it, beginning in the south. Obverses generally showed a profile, and later sometimes a frontal, bust. A profound break with tradition came when Theodebert I (533/534–547/548) substituted his own name on his gold for that of the Byzantine emperor—a change that in turn was to influence Visigothic gold. The right of striking gold had meanwhile been widely extended, to mints presumably

Borrowings from imperial types

operated by royal permission and numbering nearly 500 in all. These were distributed over an area including not only what is now France but also the Low Countries, the Rhineland, and Switzerland. The types of Merovingian gold coins diverged increasingly from imperial models: nearly all of them were inscribed on the obverse with the name of the issuing authority, most often municipal, and on the reverse with that of the moneyer. As the Merovingian dynasty drew to a close in the 8th century, gold coinage became poorer in quality, and it gave way to the small silver denarius, of about 1.2 grams, struck in quantity. This change heralded the Carolingian revival of the denarius.

Coinage supply to Britain was interrupted when the mints of Roman Gaul were closed *c.* 395, and scarcely any gold or silver coin entered Britain during *c.* 450–550. Subsequent penetration of Merovingian gold encouraged a brief Anglo-Saxon coinage of gold thirds (see below).

Coinage in the Byzantine Empire. Inspiring many features of these transient coinages, but outliving them all, stood the currency of the Byzantine Empire. It was based on the gold solidus ($^1/_{72}$ of a pound) of Constantine—the bezant of 4.5 grams (about 70 grains) maximum, which dominated so much of European trade to the 13th century. Until the 10th century, halves and thirds were also used. This gold was proverbial for its purity until the 10th century. The fundamentally religious nature of the empire was fully reflected in the coinage: throughout 10 centuries there was scarcely a single issue that did not look directly to the Christian faith, since apart from reverse types and legends, which were purely religious, the obverses showed the emperors as specifically Christian rulers by the use of adjuncts or appropriate inscriptions.

Byzantine coinage began effectively with the reign (491–518) of Anastasius I. Thenceforth, it consisted, in addition to gold, of silver and bronze. Silver, always rather rare, consisted of the small siliqua ($^1/_{24}$ of a solidus) or keration, followed by the larger miliaresion and the still larger hexagram. Bronze was in most periods very commonly struck. Its appearance and tariffing were reformed by Anastasius, who issued large pieces marked *M, K, I,* and *E* (equal to 40, 20, 10, and five *nummi*); other multiples were found either later or locally, as *IB* (equal to 12 *nummi*) at Alexandria. Such marks of value continued until Basil I (867–886). Constantinople itself was the main mint in all three metals, which were coined also at Carthage and Ravenna. Thessalonica, Nicomedia, Cyzicus, Antioch, and Alexandria struck bronze only; at one time or another Rome struck gold and bronze, while Syracuse and Catana also contributed. The technique of gold and silver minting was generally high; that of bronze was coarse, and overstriking was common.

Major Byzantine mints

Types and legends of Byzantine coins. For gold, the earliest obverses were diademed profile busts or helmeted facing busts, both common on previous coins of eastern and western empires. The facing bust showed the emperor in military panoply with a cross in his hand or on his helmet, and, if the cross was lacking on the obverse, it appeared on the reverse. With Justin I (518–527) and Justinian I (527–565), the seated figures of the emperors were shown side by side (527). Thereafter, the facing head became more common: from the time of Phocas (602–610) it was increasingly formalized, a process that reached its climax in the 8th century. Under Heraclius (610–641) the habit began of showing the emperor with one or more of his sons; and, with figure types now more common, it was possible to show emperor and empress together or even, as with John I Tzimisces (969–976), the emperor being crowned by the Virgin, with the hand of God above. The reverses of the gold coins at first emphasized the Victory (doubtless regarded as an angel) of previous issues. Tiberius II introduced the cross potent on steps, a type destined to play a long and important part. Justinian II (685–711) was the first to use the haloed bust of Christ, who had previously been shown only on a coin of *c.* 450, in the act of marrying the empress Pulcheria to Marcian. The Iconoclasm of Leo III (717–741) and his successors banished such divine representations in favour either of the cross on steps or of imperial figures on the reverses, but with Michael III (842–867) the bust of Christ returned. From Basil I the throned Christ predominated.

The obverses of the silver coins, beginning with profile busts, thereafter included seated figures, facing busts, and purely epigraphic designs. The introduction of the larger hexagram by Heraclius in 615 allowed fuller scope for later designers, whose reverses often consisted of a cross on steps or a bust of Christ surrounded by inscriptions; from the 10th century the cross bore a central portrait medallion of the emperor himself.

In bronze coinage there was at first less flexibility. The earliest types were, obverse, a profile bust and, reverse, a cross and mark of value. Under Justinian I the facing bust prevailed, and in his 12th year he introduced the dating of his bronze coins on the reverse, in the form *Anno XII;* the inclusion of a regnal date was thereafter normal on bronze until Constans II (641–668). From the time of Justin II (565–578) the obverses showed two or more standing imperial figures combined (until Basil I) with the mark of value. From the 10th century the reverses were taken up wholly by three or four lines of inscription; and the anonymous bronze coins of John Tzimisces combined such a reverse, reading *Iesus Christus Basileu(s) Basile(on),* with a new obverse showing the facing bust of Christ designated *Emmanuel.*

Byzantine bronze types

The orthography of Byzantine coin legends became remarkably complex as the Latin and Greek alphabets were increasingly mingled and individual letters took on new or specialized forms and words were severely abbreviated. At first the inscriptions were purely Latin, the emperor's names and titles being in the conventional form *D(ominus) N(oster)—P(ius) F(elix) Aug(ustus).* Even before Anastasius, however, *Perpetuus* had been a variant for *P.F.*, and, abbreviated in the form *PP,* it finally prevailed. In the 7th century, Greek letters were more commonly mixed with the Latin in such legends as that of Justinian II, when he styled himself *Servus Christi;* and in the later 8th, the general shift to Greek from Latin conceptions was plain in the emperor's new title of *Basileus.* Comparatively long votive inscriptions, as "Lord, help thy servant," and metrical inscriptions (a practice more common in Asia than in Europe) began in the 10th century.

Economic role of Byzantine coins. Byzantine gold coinage, until its debasement from the 10th century, was immensely important in the economic life of the Levant and western Mediterranean. The total output of gold was great, and its influence can be judged partly from the distribution of the coins themselves and partly by the typological influence exerted by the Byzantine upon other coinages, from the first Arab-Sāsānian gold of the East to that of Italy and Gaul in the West. In the 5th and 6th centuries, Byzantine solidi accumulated in the Baltic area, doubtless in payment for furs; and, in the 6th and 7th, solidi of a slightly lighter weight were hoarded in France, the Low Countries, Scandinavia, Germany, the Balkans, Russia, the Levant, and northern Africa. In these last two regions Byzantine gold competed from the 7th century with the increasing output of Arab gold dinars.

Charlemagne and the Carolingian coinages. While the bezant and dinar maintained gold currency along the Mediterranean, northern Europe from the 8th century suffered a shortage of gold and turned its almost exclusive attention to silver, inherently more convenient as a unit of exchange. A previous Merovingian tendency to introduce silver alongside gold was carried much further when the Carolingian ruler Pepin the Short (751–768) replaced gold by silver, introducing the denier, which was to be the basis of all medieval coinage in the north. His new coin was wider and thinner than previous silver pieces. The normal types were simple—obverse *R P* (for *Rex Pepinus*), reverse *R F* (for *Rex Francorum*).

Coinage of Pepin the Short

Charlemagne (768–814) reorganized northern currency in a way that affected it permanently. Coining at first simply as *Carolus R F,* he defeated the Lombards in 774 and entered Rome, becoming king of Lombardy as well. His deniers were later made wider and still heavier (about 25 grains), and he introduced the smaller and subsidiary obole, or half-denier. The main types of his deniers were threefold: the monogram of his Latinized name, Carolus;

a temple (sometimes a gateway); and, more rarely, a portrait. Monogram deniers were coined in France, Germany, northern Italy, and northeastern Spain; temple deniers were also widely struck, often inscribed *XRISTIANA RELIGIO*, though this legend was sometimes replaced by the name of a major French mint city. On Christmas Day 800, Pope Leo III crowned Charlemagne as Roman emperor, and, thenceforth, his deniers, either with the temple type and "Christian" legend or with a mint name alone, styled him *Kar(o)lus Imp. Aug.*, sometimes adding *Rex F(rancorum) et L(angobardorum)*. His mints lay mainly in France, the Rhineland, and the Low Countries.

Louis I (814–840) continued his father's monetary system with little essential change. But the infringement of his minting rights emphasized the economic importance of northern ports, especially the Frisian Duurstede, from the neighbourhood of which emanated large numbers of copies of his gold sous and half-sous. These portrait coins originally were designed presumably for presentation to the Holy See, since the reverse bore the inscription *MVNVS DIVINVM* around a cross. They were struck sparingly, and no Carolingian gold thereafter appeared. Charlemagne's pattern of coinage, sometimes varied, was extended to Lotharingia, with such powerful mints as Cologne, Metz, Trier, and Strasbourg. From the time of the French kings Louis II and III (877–882) the Carolingian currency pattern weakened, and feudal coinages made their first appearances. Louis IV d'Outremer granted coinage rights to the archbishop of Reims as early as 850, and the system was swiftly developed in the 10th century, concessions being made to a large number of ecclesiastical foundations and even in a few cases to lay lords as well. In Spain, Carolingian mints were established only in the extreme northeast, at Barcelona, Ampurias, and Gerona. The kingdom of Aquitaine, under Charlemagne, was reserved to the Frankish king's son, and its coins were modeled on the Carolingian pattern. Northern Italy was an integral part of the territories controlled by the earlier Carolingians, but from the mid-9th century changes began to show: the deniers of Pavia and Milan, though retaining Carolingian types, became broader and thinner, with wide rims like those of the later German bracteates (see below). Venice, a republic from the late 7th century, ruled by a doge under Byzantine protection, did not coin until the 9th, when it struck deniers for the Carolingians; but after Lothair I it omitted mention of the imperial name.

Papal coinage

At Rome papal coinage began with Adrian I (772–795), Byzantine in style and types, but after Charlemagne's visit in 774 all deniers (except during an imperial interregnum) were struck jointly with the pope's monogram and the emperor's name, until 904; thenceforth, the papal name appeared in full and alone. The principalities of Beneventum and Salerno and the duchies of Naples and Amalfi fell within the Byzantine–Arab orbit, and their gold, silver, and bronze showed these beside Carolingian influences; bronze coins in particular followed Byzantine models, while the gold tari of Salerno were curious fractional copies of Arab dinars. In central Europe, Carolingian coinage was not reflected east of the Rhineland, but in the north the imitation of Carolingian money in or around Duurstede bred more distantly derivative issues elsewhere, possibly even in Scandinavia; these were, in effect, silver deniers, but their types, with their emphasis on ships and animal designs, show them to belong to the Nordic, as opposed to the Teutonic, stream of monetary design.

THE LATER MEDIEVAL AND MODERN COINAGES OF CONTINENTAL EUROPE

The change of power from Frankish to German emperors in the 10th century saw the silver denier extended into central and northern Europe. In the East the decay of the Byzantine Empire was reflected in the debasement of its gold coinage to electrum; after the temporary fall of Constantinople to Western crusaders in 1204, Byzantine tradition was carried on in the silver coinages of the derivative empires of Trebizond, Nicaea, and elsewhere. The revival of gold coinage in Italy in the 13th and 14th centuries, promptly copied elsewhere, led to the need for a silver denomination larger than the denier, and the grosso and its equivalents soon spread widely. From the 14th century coinage began to lose its Gothic stiffness: the Italian Renaissance pointed the way to naturalism in portraiture and to greater fluency of ornament. In the 15th century the first experiments were made with mechanical methods of coining, and by the 16th the new techniques were being generally adopted (see below *Techniques of production*). The traditionally privileged nonregal mints were incapable of producing the mechanical power needed for the intensive coinage not only of the large gold denominations resulting from the influx of Spanish-American treasure after 1493 but also with the equally large silver thalers, or dollars, beginning to be produced with silver from the German Joachimsthal mines. Multiplication of gold and silver coinages, and their larger denominational values, emphasized the need for token coinages, which were produced from the 17th century. Britain was effectively on the gold standard from the end of the 18th century, together with Portugal, but it was not until the second half of the 19th that continental Europe followed suit. Paper currencies of this period were fully redeemable in gold coin, but the gold standard was abandoned during World War I; since then, paper has been redeemable effectively only in base-metal alloys.

Renaissance developments

The coin types of the later medieval period were relatively crude. Portraiture, schematically stiff on later Byzantine money, was revived with striking realism most notably in Renaissance Italy and thereafter flourished. Reverses revealed feudal influence in shields of arms and civic emblems. These developments set the general pattern of modern coinage, usually with an obverse portrait and some form of national badge or arms on the reverse. From *c.* 1800 onward this pattern was standardized to a large degree.

Portugal. Coinage began in Portugal, after the expulsion of the Moors, with Afonso I (1128–85), whose gold maravedis, copied from the gold of the Berber Almoravids, retained certain Arab features in design. Some base silver was also struck. Rights of coinage were, from the start, reserved to the kings, almost exclusively. Peter I (1357–67) reformed the coinage on the basis of the gold dobra of about 4.9 grams, with types copied from those of contemporary France: obverse, king enthroned; reverse, ornamental cross. There was a similarly imitative silver gros tournois (based on the weight standard of Tours, Fr.). Peter's successors developed his system. Copper was struck from the 15th century. From the 16th to the 18th century, gold was coined in quantity and in denominations of handsome size down to the half-escudo. In the 19th century the basic gold denomination was the crown. In the 20th century token denominations (in terms of centavos) have prevailed in various alloys, though silver was introduced in 1954 for the 10-escudo piece and for certain purely commemorative issues.

Spain. As in Portugal, the coinage struck after the expulsion of the Moors was almost without exception regal. That of Navarre started under Sancho III Garcés (*c.* 1000–35) with deniers of Carolingian influence. The series of Castile and León began with similar pieces under Alfonso VI (1065–1109), and that of Aragon under Sancho Ramírez (1063–94). Among the earliest gold was that of Alfonso VIII of Castile (1158–1214), copying an Arab gold dinar but with Christian professions in its Arabic script. Gold portrait doblas appeared under Sancho IV of Castile and León in the 13th century, and the portraiture under Pedro I in the 14th was of high quality. Gold coinage multiplied in the 15th century, with Henry IV coining huge pieces of superb Gothic style; silver and billon were also in good supply. The union of the crowns of Castile and Aragon in 1479, and subsequently the influx of American precious metals, resulted in an abundant coinage in gold (the excelente and its multiples) and silver (the real and its multiples)—the silver piece of eight being the famous Spanish dollar. This last denomination enjoyed enormously wide currency, and its type (obverse, royal portrait; reverse, Pillars of Hercules with *PLVS VLTRA* on scroll) was universally known.

Influx of American precious metals

France. The dynasty of Hugh Capet (987–996) made no immediate change in the previous Carolingian coinage

system: deniers and their halves, the oboles, continued, but tended to decline in fineness. Feudal deniers began to appear in abundance beyond Capet's kingdom of north central France; the most important and numerous were issued from the 10th century by the abbey of St. Martin at Tours, with a "castle" type destined to exert wide influence. This monnaie tournois was lighter than the royal monnaie parisis (based on the Paris weight standard), generally in the ratio 4:5. Louis IX in and after 1262 reformed the coinage. The sou became in 1266 the silver gros tournois, $^{23}/_{24}$ fine and weighing about four grams; its types continued the "castle" of the denier tournois but with concentric inscription and ornament frequently imitated. With this there appeared a gold écu, with the royal lilies on a shield. Subsequent development down to the 15th century emphasized more and larger gold denominations; silver continued, often debased. Design reached magnificent heights of Gothic splendour, seen in the *masse d'or* ("sceptre of gold"), *mouton d'or* ("Paschal Lamb"), *ange d'or* ("angel of gold"), and *franc d'or* (franc ["free"], a term first applied to a coin of John II, minted in 1360 to commemorate his ransom from the English). The Anglo-Gallic issues of the time were comparably beautiful. Feudal coinage was severely limited, that of Brittany and (at

Louis XIII silver écu blanc (louis d'argent), Paris, 1643; the dies for the coin were engraved by Jean Warin. In the British Museum. Diameter 44 mm.

Reproduced with permission of the trustees of the British Museum, photograph, Ray Gardner for The Hamlyn Publishing Group Limited

first) Aquitaine being most important. Types in Aquitaine later showed some English influence, while in the gold of Provence that of the Florentine florin was noticeable. In the 16th century broad, thick silver coins were adopted, familiarized by the testons (from *testone,* which means "head") of Italy; these, together with the gold écus, set the general pattern. Early in the 17th century the use of machinery for coining was the subject of experiments by Nicolas Briot; both he and Jean Warin were famous for their technique and style under Louis XIII. The late 17th and 18th centuries, though their coinage was of considerable external magnificence, were not devoid of monetary difficulty. Louis XV suppressed independent local minting, Strasbourg being the last provincial mint to survive, though royal branch mints continued. Under the Revolution Louis XVI coined first as constitutional king, in gold, silver, and copper; but from 1793 the issues were wholly republican, with the inscriptions *République français, Liberté,* etc., and the symbols (cap of liberty, cock) that have survived in modern French coinage. The precious metals were in short supply; gold and silver were demonetized and paper took their place, together with copper. In 1793 the decimal system was adopted, in terms of francs, decimes, and centimes, coins now being dated by the Revolutionary era; gold coinage was effectively lacking until the time of Napoleon. From 1866 France was joined with Belgium, Italy, and Switzerland in a monetary convention defining the denominations, quality, and weight of gold and silver coinage in terms of francs. In the 20th century alloys were introduced, and the Vichy government of Henri-Philippe Pétain also used zinc, iron, and aluminum. From 1950 paper money was increasingly replaced by alloy coins, the "heavy" revalued franc being introduced in 1959.

20th-century materials

The Low Countries. In Merovingian and Carolingian

The gold vieil heaume of Louis de Mâle, count of Flanders, 1367, one of the largest Flemish gold coins. In the Fitzwilliam Museum, Cambridge. Diameter 35 mm.

By courtesy of the Fitzwilliam Museum, Cambridge. Collection of Professor P. Grierson

periods a few mints operated in the Low Countries. Subsequently the area was divided among a number of dukes, counts, seigneurs, and ecclesiastics. In the 16th century the Low Countries passed to the House of Austria, and the daalder (dollar) appeared. English military operations were accompanied by the issue of gold pieces. The 16th century produced some remarkable siege pieces from Amsterdam, Bergen op Zoom, and elsewhere. With the establishment of the Kingdom of Holland under Louis Napoleon in 1806, coinage began to conform with that of the Napoleonic Empire. Belgium emerged as an independent kingdom in 1831, and in 1860 adopted a cupronickel alloy for its French- or Flemish-inscribed or bilingual coinage.

Switzerland. The coinage of Switzerland illustrates its varying fortunes. First there was the gold money of the Merovingian kings, among whose mints were Basel, Lausanne, St. Maurice-en-Valais, and Sitten (Sion). The silver deniers that Charlemagne made the coinage of the empire were issued by fewer mints. The dukes of Swabia began to strike at Zürich in the 10th century, and the empire from the 10th to the 13th century granted the right of coinage to various ecclesiastical foundations. Bern was allowed a mint by the emperor Frederick II in 1218, and other towns and seigneurs subsequently gained the same right. The demi-bracteate appeared about the middle of the 11th century, and about 1125 it was superseded by the true bracteate, which lasted until about 1300. (Bracteates were lightweight silver coins so thin that they bore only a single type, repoussé [hammered into relief on the reverse], for which a special technique [including the use of wooden dies] was devised.) The Swiss Confederation developed in the 14th century, and by degrees the cantons struck their own money. These, together with the coins of some few sees and abbacies, formed the bulk of Swiss money of the medieval and modern periods. The cantonal coinage, interrupted by the French occupation, was suppressed in 1848, when a uniform currency was adopted.

Italy and Sicily. At the close of the Carolingian period the coinage of Italy fell into two main classes. In nearly all of the north, including Rome, it consisted of silver deniers of Carolingian derivation, mainly struck at Pavia, Milan, Lucca, and Verona. At Venice and over most of the south the dual influences of the Byzantine and Arab empires were prominent. Monetary fashions were shown in the coinage of Sicily struck by the Normans. Robert Guiscard in 1075–85 struck small gold coins called taris of almost wholly Arabic appearance, together with bronze of Byzantine style. Roger I of Sicily Latinized the bronze, and Roger II coined silver ducats of Byzantine type; Arab-style gold taris still continued for commercial reasons, since the great Fāṭimid coinage was then the currency of all western Muslims. After southern Italy and Sicily had fallen to German power, Frederick II (1212–50) restored a Latin coinage of gold, of splendid style and execution and good fineness, in proto-Renaissance style. His gold augustale (patterned after the aureus) and their halves, struck *c.* 1231 at Brindisi and Messina, were accompanied by billon deniers. Sicily soon passed to Charles I of Anjou (1266–85), and its Angevin coinage, like that of Naples,

assumed the French medieval style, succeeded in turn by that of the Aragonese kings.

Coinage of the northern Italian cities

In northern Italy leading cities were issuing silver with a free choice of types—portraits, badges, or figures of patron saints and others, with explanatory legends. Mantua celebrated Virgil; Florence from *c.* 1189 showed its lily with St. John the Baptist; and Genoa chose the *janua,* or eponymous gate. Venice, abandoning the imperial name early in the 12th century, set a precedent *c.* 1192 in the issue of the larger silver grosso or matapan, using the henceforth familiar types of Christ on the reverse and, obverse, St. Mark presenting the gonfalon (the banner of the republic) to the doge. The influence of the gold coinage of Frederick II on such cities was soon evident. Genoa was striking gold as early as 1252. Florence issued the first of its famous and profuse series of fiorini d'oro, or gold florins. The lily continued as the civic type, together with the standing figure of the Baptist. Regular weight (about 3.50 grams, 54 grains) and fineness won the fiorino universal fame and wide imitation; double florins were introduced in 1504. Venice in 1284 produced its gold ducat, or zecchino (sequin), of the same weight. Venetian ducats rivaled Florentine florins in commercial influence and were widely copied abroad. The series begun under Giovanni Dandolo continued with the names of the successive doges until the early 19th century.

At Rome no papal coins appeared from 984 until purely epigraphic types recorded the names of Leo IX and the emperor Henry III in 1049–54. Thereafter, there was a further gap until Urban V (1362–70). The Senate of Rome coined silver deniers from 1188, with the antique legend *Senatus Populus Q.R.* and figures of SS. Peter and Paul. In 1252 Brancaleone struck deniers with the seated figure of Rome and the legend *Roma Caput Mundi;* Charles of Anjou in the 13th century and Cola di Rienzo in the 14th also coined, as Roman senator and tribune, respectively. Senatorial gold ducats were introduced on the Venetian model in 1350. Papal coinage returned from Avignon in 1367 with Urban V, who assumed rights over the mint of Rome; gold, silver, and bronze later developed, with types (crossed keys, tiara, personal arms, and many different emblems) that, with few interruptions, have lasted ever since. Since 1869 papal coinage has been mainly of a commemorative nature, in silver, acmonital (stainless steel), and bronze, of denominations corresponding with the Italian state coinage.

Design under patronage

The patronage given by the popes to notable artists—*e.g.,* Francia and Benvenuto Cellini—resulted in a fine and often lavish standard of design in their coins and medals. Similar patronage was shown by the noble houses of Ferrara, Mantua, Milan, and elsewhere, whose coinages from the 15th century attained a splendid level. The size of gold and silver denominations was growing, as witness the silver teston of 1472; and the portraits made by Caradosso, Francia, and others of equal fame are among the finest small-scale Renaissance works. Later coins of still larger size of the duchies of Savoy and Florence are remarkable. Italian coinage continued to be divided among a number of kingdoms, principalities, and duchies until 1861, when Victor Emmanuel I first coined as king of all Italy. The metals were gold, silver, and bronze; alloys were introduced under Umberto I (1878–1900). Under Victor Emmanuel III (1900–46) reverse types borrowed heavily from the antique, and his later issues reflected the influence of the Fascist regime, being dated by the Fascist era from 1936 (year XIV) as well as by the Christian. From that same year, he appeared as emperor (of Ethiopia) as well as king of Italy, and after 1939 coins were struck for him, with a helmeted portrait, as king of Albania. After World War II the republican coinage of Italy, in aluminum and steel, concentrated mainly on symbols of agricultural fertility and national industry.

Germany and central Europe. Territorially, the German issues began and developed in an area that has since been many times divided and from which Austria, Hungary, Czechoslovakia, and Yugoslavia have emerged as separate states. Classification of these issues remains one of the most formidable numismatic problems.

From the 10th to the 12th century the Carolingian pattern of coinage was continued; but with the advent of the Swabians under Conrad III in 1138, unity disappeared. In the west the silver denier continued. In the east the coinage of very thin bracteates was developed. The western deniers were in part from imperial mints, scattered among a much larger number of feudal mints, representing ecclesiastical rather than lay authorities. Westphalia produced a profuse ecclesiastical coinage. That of Cologne was especially important, showing the former Carolingian "temple" combined with the linear inscription *S(ancta) Colonia A(grippinensis)*; and that of Münster was comparable in influence. This area was conservative and prosperous; the weight of its deniers was well maintained, and, although Anglo-Saxon and, later, English and Byzantine influences became noticeable, its types changed but little.

Westphalian ecclesiastical coinage

In the eastern region a sharp decline in weight led to the thin, single-type bracteates, and the designs quickly broke away from Carolingian tradition. Issued by a wide variety of authorities, many of them ecclesiastical, these coins showed a great range of human figures and portraits (saintly and secular) together with representations of churches, castles, and heraldic devices in an essentially medieval Germanic style. The difference between the heavier western deniers and the lighter eastern bracteates was perhaps partly responsible for the emergence of the Mark. This weight of solid silver, the mass of which varied from one time and area to another, stood at about $^2/_3$ of the gold pound, which equaled 240 western silver deniers.

Transition from medieval to modern coinage took place with the emperor Louis IV of Bavaria (1314–47), who introduced gold and multiplied the silver grossus already issued by Cologne under Henry VII (1308–13). Louis reduced the number of purely imperial mints. Many others operated by rights granted to the nobility, the churches, and certain municipalities, and from these henceforth appeared the bulk of German coinage, including from 1520 the large silver thalers (so called from the Joachimsthal mines in Bohemia and from which derived the word *dollar*). In the 16th and 17th centuries the thalers and their multiples, of handsome and even ornate appearance, dominated the silver currency of Germany. Thalers of Saxony and Brunswick are especially well known. The thaler continued as a unitary denomination to the 19th century in Germany proper, but in 1870 German adherence to the gold standard caused its abandonment. From 1870 the kings of Prussia as emperors coined for all Germany; henceforth, the innumerable local variations in coinage were subsumed under the gold Reichsmark of 100 pfennigs, the silver standard being abandoned. After World War I the rulers of German states abdicated or were deposed, and everywhere the value of the Mark declined to zero, its place being momentarily taken by inflated paper currencies. Silver was coined mainly for commemorative pieces between World Wars I and II, including the Hindenburg portrait pieces; zinc, aluminum, and alloys furnished the wartime currency of 1939–45. After 1948 the coins of West Germany were inscribed *Bundesrepublik Deutschland;* those of East Germany, *Deutschland* alone (with emblems of industry and fertility).

In Austria there was a ducal silver coinage in the 11th century. It remained crude until the 14th century, when Albert II (1330–58) introduced a gold florin of Florentine character. The gros appeared with Frederick III (1440–93): thereafter, development was parallel with that of Germany, with thalers taking a prominent place. Those with the portrait of Maria Theresa acquired wide popularity on either side of the Red Sea. They continued to be coined in large numbers at Vienna and London, with the date 1780, for circulation in those regions: 24,000,000 were struck in 1940–41 from British mints alone.

The Bohemian ducal coinage of deniers from the 10th to the 12th century showed Byzantine, Scandinavian, and even English influences; by the 12th century the Prague mint was developing its own style. Wenceslas II first produced the gros in 1300, and John of Luxembourg (1310–46) the first gold florins, with, obverse, crown and, reverse, rampant lion. The regal coinage of Hungary began with the deniers of Stephen I (St. Stephen; 1000–38), and the style remained crude until Charles I (1310–42) introduced

a lily-bearing gold florin and a silver gros modeled on those of Naples and Rome.

Austro-Hungarian imperial coinage

With the formation of the Austro-Hungarian Empire in 1848, the coinage of the two countries, including Bohemia, was unified. During 1857–68 the coinage conformed to the terms of a monetary convention with Germany. The coins of Austria and Hungary were differentiated from 1868: the former were inscribed in German or Latin, and the latter in Magyar. Since 1923 the republican coinage of Austria has been conspicuous for its commemorative silver coins. That of Hungary, under the regency of Adm. Miklós Horthy, emphasized the crown of St. Stephen; under Soviet domination types symbolized revolution, peace, fertility, and industry, together with architectural motifs for silver.

Czechoslovak coinage from its inception in 1918 had shown the lion of Bohemia; special coinages have commemorated St. Wenceslas (in gold) and Tomáš Masaryk and—after the Soviet occupation of 1968—Stalin (in silver). Yugoslavia, similarly an offshoot of Austria-Hungary, has a currency based on paras and dinars. That of Albania, until its domination by the Soviet Union in the early 1950s, drew heavily on classical Greek types.

Scandinavia. The origin of Norwegian, Danish, and Swedish coinages is clearly the result of the Danish conquest of England. The Runic alphabet was employed, though not by any means exclusively, on many early coins of Denmark and Norway. The Norwegian series began with Haakon the Great (*c.* 970–995), who copied the pennies of Ethelred II. In the second half of the 11th century, a coinage of small, thin pennies began, which developed into bracteates. Magnus VI (1263–80) restored the coinage, more or less imitating the English sterlings of the time. The money of Denmark began with pennies of Sweyn I (*c.* 987–1014), also copied from the coinage of Ethelred II; the coins of Canute (Cnut) the Great (1016–35) and Hardecanute (Harthacnut; reign extended to England in 1040–42) were mainly English in character. With Magnus I (reign extended to Denmark in 1042–47) other influences, especially Byzantine, appeared, and the latter was very strong under Sweyn II Estridsen (1047–74). Bracteates came in during the second half of the 12th century. The coinage is very difficult to classify until the time of Eric of Pomerania (1397). There were important episcopal coinages at Roskilde and Lund in the 12th and 13th centuries.

Sweden had very few early coins; Swedish coinage began with imitations by Olaf Skötkonung (995) of English pennies and included the usual bracteate coinage. The money was restored by Albert of Mecklenburg (1364–89). The thaler was introduced by Sten Sture the Younger (1512–20). The money of Gustav II Adolf (1611–32) is historically interesting. Under Charles XII (1697–1718) there was highly curious money of necessity (*i.e.*, a coinage struck to fulfill a need, usually in time of war and siege, but with inadequate technical means available). The small copper daler was struck, sometimes plated; types included Roman divinities. During the 17th and 18th centuries there was a large issue of enormous plates of copper, stamped with their full value in silver money as a countermark.

Modern Norwegian coinage, like that of Denmark, is remarkable in including certain denominations pierced with a central hole. That of Sweden has included some large commemorative pieces of silver. In Denmark the Copenhagen mint has produced a colonial coinage for Greenland. Iceland, formerly joined with the Danish crown, has struck republican coins since 1944.

Poland. After monetary beginnings derived from Germany, Poland developed a 16th-century coinage in gold, silver, and billon that reflected its status as the greatest power in eastern Europe; its thalers were especially remarkable for fine portraiture and decoration, including the superb pieces coined by Danzig after 1567, when this area sought Polish protection. Dismemberment of Poland in the 17th and 18th centuries was followed by fluctuations in status, which have continued ever since. The coinage of independence after World War I celebrated national symbolism and national heroes, such as Józef Klemens Piłsudski and John III Sobieski. On the coins produced during German occupation in World War II and during Soviet control thereafter, the Polish eagle has been a prominent emblem. Danzig struck its own coinage (in pfennig and gulden) while a free city (1920–39).

Russia and the Balkans. The earliest Russian coins were produced for the princes of Kiev in the 10th century and showed strong Byzantine influence. The staple coinage later came to consist of small silver kopecks and their halves (dengi) of Mongolian derivation. Ivan IV (1547–84) standardized the types of the dengi as "Tsar and Grand Prince of All Russia," showing a uniform design of a mounted lancer. From the 15th to the 17th century unstable social and economic conditions were reflected in clipping and counterfeiting, until reforms began in 1654. Peter the Great (1689–1725) reorganized the currency: gold was coined regularly from 1701, and silver rubles and billon kopecks also appeared, together with copper fractions. In 1725, after Peter's death, copper "plate money" was briefly produced (as in Scandinavia) at Ekaterinburg. Recoinage on a large scale occurred in 1741. Under Catherine II (1762–96) copper rubles of great size were briefly struck, and substantial five-kopeck pieces were in common production; Russian copper was also produced in Georgia. In the 19th century, Russian coinage followed conventional lines apart from the short-lived introduction in 1828 of platinum for pieces of 3, 6, and 12 rubles. The silver ruble, however, remained the monetary basis, worth 100 kopecks until a change to gold in 1897. Soviet issues were mainly of alloys, with scarce silver and, very rarely, gold; types usually included the hammer and sickle and the star, together with allusions to industry and agriculture, though after the Revolution the Russian eagle was used at first.

Currency of Peter the Great

Finland, as a Russian grand duchy from 1809, struck in gold, silver, and bronze until declaring independence in 1917; since then, its coins have shown the Finnish lion. Latvia coined as an independent state from 1918 to 1940 and again from 1992; Lithuanian independence, similarly until 1940 and again from 1992, was reflected in autonomous coinage.

The medieval coinages of the northern Balkan states are of great morphological interest. They are chiefly silver grossi, showing a mixture of Byzantine and Venetian influences. The Bulgarians had a regular silver coinage from Ivan Asen I (1186–96) to Ivan Shishman (1371–93). Modern Bulgarian coinage began in 1879. The Serbian coinage lasted from Stephen Vladislav I (1234–43) to the mid-15th century. There was also a coinage of the bans (local officials) of Bosnia (late 13th to 15th century). The independent city of Ragusa is remarkable for the bold Roman style of its early copper (13th century) and for its rich and varied later issues.

In Romania a princely coinage from 1866 became a royal one, of orthodox pattern, from 1881; the 20th-century types, until the fall of the monarchy in 1947, were remarkably varied. That of Greece began with the republican government of 1828: the basis was the silver phoenix of 100 lepta. This was followed, under the monarchy from 1833, by the drachma of similar value. The 20th century emphasized the types of ancient Greece, though modern issues have broken from this tradition.

The later Byzantine empires. From the time of Basil II (976–1025) the fabric of the gold nomismata (successor of the solidus) and also of the silver began to change, from using a narrower, thicker blank (flan) to one wider and thinner, which was also given a curious cup shape, hence the name *nummi scyphati* (cup money); gold scyphati declined in purity until, under Nicephorus III (1078–81), they were very base. Silver remained generally scarce; the issue of bronze became uneven. New conventions in legends and types were introduced: Constantine IX (1042–55) showed on his silver an invocation to the Virgin in iambic trimeter; and an invocation used by Romanus IV (1068–71) took the form of a hexameter, carried over from obverse to reverse. Figures of the saints appeared in the 12th century. At the same time, the intrinsic quality of the coinage had sunk to a level of desperate confusion, seen most plainly under Alexius I Comnenus (1081–1118), whose "gold" was sometimes no more than billon or even bronze. The influence of Western types was seen

Legends and types

powerfully in the bronze struck by Andronicus II with, reverse, a cross pattée surrounded by a circular inscription within a double border. Western influence continued in the 15th century, especially under John VIII Palaeologus, whose visit to Italy in 1438 (when Pisanello made his splendid portrait medal) doubtless familiarized him with the designs of the grosso and gros, which were imitated unmistakably on John's silver and from which derived the English groat. By this time the Byzantine idiom in coinage was virtually dead.

With the capture of Constantinople by the crusaders in 1204, the power of the Byzantine Empire was split among a number of smaller authorities, of which the "empires" of Thessalonica and Nicaea were short-lived: in both, the coinage (where attributable) was of normal Byzantine character. The empire of Trebizond, however, continued a separate existence until 1461; its small silver pieces, called "Comnenian white money," were prized for their purity and enjoyed a wide currency. Through such means the influence of Byzantine types was exerted on the contemporary coinages of Armenia and elsewhere in Asia Minor.

(C.H.V.S.)

COINS OF THE BRITISH ISLES, COLONIES, AND COMMONWEALTH

Ancient Britain. The earliest coinage of Britain consisted of small, cast pieces of speculum, a brittle bronze alloy with 20 percent tin. These coins copied the bronze of Massilia (Marseille) of the 2nd century BC and circulated, mainly in southeastern Britain, early in the 1st century BC; their relationship with contemporary iron currency bars is uncertain. At the same time, uninscribed gold coins of the Gaulish Bellovaci, a tribe located near Beauvais, imitated from the famous gold stater of Philip II of Macedon, were being introduced, probably by trade. The first Belgic invasion, *c.* 75 BC, brought variants of these, from which arose a complex family of uninscribed imitations. The study of distribution in Britain has ascribed them to fairly well-defined tribal areas in the south and east; some are crude, but the best illustrate the peak of Celtic art in Britain. The gold was of variable purity. After the second Belgic invasion (following Caesar's raid in 55 BC) the coinage entered a historical phase through the addition (in Latin, and with Roman titles, etc.) of the names of kings. Roman influence under Augustus prompted the introduction of silver and copper to reinforce the gold and the Romanization of previously "Celtic" types. Claudius' conquest in AD 43 ended native coinage except for crudely cast billon pieces long continued in the Hampshire and Dorset area; the gold of the tribe of the Brigantes in what is now Yorkshire was the last to disappear.

Roman Britain. Unofficial copies of Claudian bronze were produced in Britain to alleviate the shortage of official Roman coinage after the conquest. Thereafter, no coinage was produced until the reign of the usurper Carausius (AD 286–293), who coined profusely in orthodox Roman fashion at Londinium (London) and elsewhere in gold, silver, and copper; the same was done briefly by Allectus, his murderer (AD 293–296). Diocletian's London mint was continued under Constantine until AD 324; thereafter, except under Magnus Maximus (AD 383–388), whose usurpation was legitimized by the Eastern emperor Theodosius I, Britain lacked an official mint, being supplied with coinage mainly from Gaul. Imitative bronze pieces, however, appeared in the 3rd century and continued to be made in the 4th.

Early Anglo-Saxon coins. Infiltration of Merovingian gold from France in the 6th century prompted the issue of Anglo-Saxon gold "thirds" in the 7th; solidi were only very rarely struck, because of their high intrinsic value. Output, never great, was confined chiefly to the London–Kent area. The London mint, almost certainly episcopal, signed its coins with the name *LONDVNIV;* Kentish coinage was mainly regal. In addition, there were a perhaps small Mercian series and another from York. A further series, copied from late 4th-century Roman prototypes, was struck *c.* 650, when the gold content was fast diminishing. Gold coinage soon gave way to that of small thick silver sceats (meaning "a portion"; about 1.29 grams, or 20 grains) of essentially different style. Some had Runic legends, including the name Peada, supposedly a reference to the king (flourished 656) of Mercia; most, however, were nonregal, and their legends are Latinized. Types were varied, and some almost certainly originated in Frisia, where sceats are found in large quantities, denoting the trading connection that called for their use; these show animal and floral design. In the south the sceats lasted until *c.* 800. Small silver sceats were developed in the mid-8th century in Northumbria, where they quickly gave way to copper, which lasted until *c.* 850.

The London mint

Anglo-Saxon penny coinages. English coinage proper began with the silver penny of Offa, king of Mercia (757–796). It was first struck at around the weight of the sceat, from about 790, and its weight increased to about 22½ grains (equal to 240 to the Tower pound; the standard pound used by the Royal Mint until its replacement in 1526 by the troy pound, whose name derives from the French city of Troyes, site of a major medieval fair). The new pennies showed Carolingian influence in their broad, flat forms. Their designs, however, insofar as they were not influenced by late Roman coin portraiture, displayed a brilliant originality (both in Anglo-Saxon portraiture and also in pattern design and decorative lettering), which had no equal for some centuries. Offa's coinage, though minted expressly for him as *Rex Merciorum,* was mainly current in the southeast and was probably struck at Canterbury. Evidence for this lies in the fact that the moneyers of Offa were also those of the kings of Kent, and the coins of archbishops of Canterbury, including Jaenbeorht (died 792), bore the names of Offa and his successor Cenwulf: under Ceolwulf (821–823) the mint name of Canterbury appeared on the coins. Offa struck pennies with the portrait and name of his wife, Cynethryth, as *Regina M(erciorum)* and also issued gold pieces copying a 774 dinar of the caliph al-Manṣūr but with the addition of *OFFA REX.* Ceremonial gold coins, like Offa's, all now represented by unique examples, were minted, perhaps partly to pay the Romescot (an annual tax to the papal see), by Archbishop Wigmund of York (837–854?), Edward the Elder (899–924), Ethelred II (978–1016), and Edward the Confessor (1042–66).

Offa's coinage influenced design under the kings of Kent and East Anglia, as can be seen in the coinage of the Wessex kingdom, which was produced first at Winchester, then, after the Battle of Ellendun in 825, at Canterbury, still the only permanent mint south of the Humber. Under Aethelwulf (839–858) a uniform type of coinage was achieved for all of southern England except East Anglia. The Viking invaders, from *c.* 870, left an important mark on English coinage, with new designs of northern European derivation. York and Lincoln were their principal mints, from which numerous memorial coins of SS. Peter and Martin were issued. Meanwhile, Alfred (871–899) greatly extended the Wessex kingdom, as shown by his operation of mints: Canterbury (still much the largest), Gloucester, Exeter, Winchester, London, and possibly Oxford. His coins were of careful workmanship and showed Viking influence. In the 10th century the power of English kings spread quickly northward. Under Athelstan (924–939) there were nearly 30 mints at work, mainly southern and central but reaching to Chester; under Edgar (959–975) there was much more uniformity of type. The Council of Grateley under Athelstan had enacted that each permitted mint was to have but one moneyer, with specified exceptions; London, for example, had eight. By the time of Ethelred II more than 70 mints were at work; London, Winchester, Lincoln, and York were the largest and most profuse. From about this time the types were generally standardized: obverse, king's portrait, and, reverse, some cruciform design.

Viking influence

Post-Conquest coinage. The Norman Conquest of 1066 made little change in the mint system or in the coinage (though the facing portrait acquired great popularity); the pre-Conquest moneyers stayed in office and struck coins for William I. After his reign the number of mints tended to decline. The pennies of William II have nothing in their legend to distinguish them from his father's issues, but it is possible to allot eight types to William I and five to

his son. Forgery gave Henry I much trouble, and one step he took to prevent it was to issue his later coins with a snick in the edge to show that the silver was good. He also coined round halfpence; previously, silver pennies had had to be halved or quartered to produce a smaller denomination. The civil wars of Stephen's reign produced many interesting coins, such as those struck in the claimant Matilda's name as *Imperatrix* and the pennies of Eustace Fitzjohn and other barons, very much on the pattern of feudal issues in France.

Henry II ceased the regular change of types customary since William I's reign and struck one type until 1180. As a result the work of the English mints reached its lowest level. His short-cross penny, so called from its reverse design, first issued in 1180, remained unchanged—including the name *Henricus*—not only by Henry II but also by Richard and John and Henry III until 1247, when Henry III coined the long-cross penny with the arms of the cross extended to the edge of the coin to discourage clipping. He also reduced considerably the number of mints. Edward I subordinated all mints to the authority of the master worker in London, William de Turnemire. In 1279 he introduced a new type of penny, with, obverse, bust of the king and, reverse, long cross with three pellets in each angle, a type that was much imitated abroad and persisted on silver until Henry VII. The moneyers' names disappeared from the reverse legends, and their place was taken by the name of the mint (*e.g., CIVITAS LONDON*). Edward I also struck halfpennies and farthings to replace the cut pennies that had hitherto done duty for small change. He also introduced a groat, or fourpenny piece, but this larger coin did not establish itself until Edward III's reign. The coins of Edward I, II, and III can be distinguished only by a minute study of detail. Privileged ecclesiastical mints still continued active.

Henry III had attempted in 1257 to issue a gold coinage by striking the gold penny (45 grains) of the value of 20 pence silver, later raised to 24; but the difficulty of relating gold to silver proved insuperable, and the coinage was withdrawn. In 1344 Edward III issued his fine gold series—florin, leopard, and helm (½ and ¼ florin)—but his attempt to introduce a gold currency failed. A gold coinage was finally established in currency in 1351 with a noble of 120 grains of gold and its subdivisions, the half- and quarter-noble. In the same year, the silver penny was reduced to 18 grains and the groat issued (on Flemish models). The noble was valued at six shillings and eightpence (½ mark). Its obverse, the king in a ship, is supposed to allude to the naval victory off the Flemish city of Sluis in June 1340. The reverse type is a floreate cross with considerable ornamentation. The weight of the noble was reduced by Henry IV in face of foreign competition. Edward IV distinguished his noble by a rose on the ship (rose noble, or ryal) and raised its value to 10 shillings, while a new gold coin, the angel, was introduced to replace the old value of the noble; the penny was reduced to 12 grains. The angel is so called from its type of St. Michael and Lucifer. The reverse is a ship with a cross in front of the mast. (In the 16th century the angel became the piece given to those touched for King's Evil [scrofula] in the belief that the king's touch could cure. It was struck for this purpose down to the reign of Charles I, and small versions were struck by the later Stuarts and pretenders, but it was not again issued as legal tender.)

Establishment of gold coinage

The next important change in the coinage was the introduction in 1489 of the sovereign, a splendid gold coin of 240 grains, current for 20 shillings, with, obverse, Henry VII seated on an elaborate throne and, reverse, a Tudor rose with central shield of arms. Henry also issued the first English shilling, a handsome, though scarce, coin with a fine portrait, probably by John Sharp, formally appointed engraver in 1510. Henry VII altered the types of the smaller silver coins by replacing the three-centuries-old cross and pellets by a long cross and shield, while the inscription *POSVI DEVM ADIVTOREM MEVM* ("I have made God my helper") took the place of the mint legend; the stereotyped bust was replaced on the groat by an excellent profile portrait and on the penny by the king seated. Henry VIII debased the gold coinage and reduced the weight of the sovereign, the reverse type of which was now the royal arms supported by a lion and dragon. He introduced the gold crown of five shillings, with its half, raised the angel to seven shillings and sixpence, and introduced the George noble—so called from its type of St. George and the Dragon—to take the angel's old value. In 1544 he issued the base shilling, or teston, of 12 pence and debased the silver coinage. When Edward VI again restored a coinage of fine silver, he introduced the silver crown of five shillings (the first English coin dated in Arabic numerals), which took the name of the gold piece of the same value introduced a few years earlier. The reign of Mary is notable for the appearance of the portrait of her husband, Philip II of Spain, on the shilling.

Coinage under Elizabeth I

Elizabeth I continued her father's denominations and restored the purity of the silver coinage. She soon discontinued the groat, Edward VI having introduced the silver sixpence and threepence, although she continued its half, the twopence. Her "portcullis," or trade coinage for use by the newly incorporated East India Company, appeared in 1600–01. She also experimented with machinery for coinage, although the insistence of the moneyers on their immemorial right to use manual methods delayed its establishment until after the Restoration. James I introduced a number of new gold coins, the most important being the "unite," or sovereign (20 shillings), so called from its legend (*Faciam eos in gentem unam* ["I will make them into one race"]) alluding to the union of the crowns of Scotland and England. Charles I made no changes in the coinage until the Civil War (when Parliament coined in London and the King's mint traveled with him); the King's financial difficulties added many new coins to the English series. These included 20-shilling and 10-shilling pieces in silver, the large gold £3 pieces of Oxford, and the fine Oxford silver crown, with a view of Oxford below the usual type of the king on horseback, made by the engraver Thomas Rawlins, employed at the Oxford Mint (1642–46) under its master, Thomas Bushell; the siege pieces rudely struck on silver plate at various Royalist strongholds show to what straits the King's party was reduced. Under James I and Charles I are found the first English copper coins, the "Harrington" farthings, which were struck under contract. From 1649, copper tokens, mainly of farthing value, were produced in large numbers by many municipalities and private traders. The coinage of the Commonwealth (1649–60) is remarkable for the simplicity of its types, and this is the only period of English coinage when the legends have been in English. Coins struck with the lord protector Cromwell's bust and superscription, although not uncommon, apart from the 1656 half crowns, seem never to have circulated.

Modern coinage. The modern coinage dates from the reign of Charles II. After issuing the old denomination of hammered money in the first two years of his reign, he replaced the unite, or broad, in 1662 by the guinea, so called from the provenance of its gold. This was a 20-shilling piece. It was not until 1717, after various oscillations, that its value was fixed at 21 shillings. His silver coins were the crown, half-crown, shilling, and so on, all regularly and beautifully struck on the new mill that was then established at London's Tower Mint. In 1672 he introduced the copper half-penny and farthing with the Britannia type. The finest coin of his reign is not a regular issue. It was the "Petition" crown made by Thomas Simon, engraver at the mint under the Commonwealth, and bears on the edge a petition to the King that he might be given the same office under the restored monarchy. For the great recoinage under William III, provincial mints were briefly opened at Bristol, Exeter, Chester, Norwich, and York. Of 18th-century coinage mention may be made of the practice of recording the provenance of the metal of particular issues, as in the *VIGO* issues of Anne struck from captured Spanish bullion in 1702, the *S(outh) S(ea) C(ompany)* silver of George I, and the *LIMA* coinage of George II made of bullion brought by Admiral Anson from his voyage around the world. Toward the end of the century the scarcity of government silver was largely made good by Spanish dollars, and by tokens issued by the Bank of England. The deficiency in copper, briefly remedied by

The "Petition" crown

George III "cartwheel" copper twopence struck not at the Royal Mint, London, but under contract at the Soho Mint, Birmingham, using steam-powered coining presses, 1797. In the British Museum. Diameter 40 mm.

large "cartwheel" issues, was made up by private issues of vast numbers of tokens. In 1816 a great recoinage took place with the introduction of the sovereign and silver coins, each with Benedetto Pistrucci's design, St. George and the Dragon. Britain was on the gold standard from 1821. In 1848, the two-shilling piece (florin) was issued and proved a most popular coin. The double florin, which was first issued in 1887, did not take the public fancy; the practical disappearance of the crown piece from circulation also reflects the public dislike of large coins, though commemorative crowns have remained popular.

The gold sovereign disappeared from internal currency in 1914 after a career of 300 years, but it has continued to be struck in irregular quantities for export abroad. Silver was alloyed up to 50 percent in 1920 and in 1947 gave way to cupronickel: the silver threepence was replaced by an angular coin of nickel-brass.

Decimal currency

On Feb. 15, 1971, the U.K. currency was decimalized. With 100 "new pence" to the pound, the decimal coinage was based on denominations of these new pence (½ [since demonetized], one, two, five, 10, 50); the sixpence coin continued briefly as a 2½-pence coin before being phased out, as were the old penny and threepence coins. On April 21, 1983, three versions of a £1 coin were introduced bearing the head of Elizabeth II, obverse, and the royal coat of arms, or the emblematic leek (Wales), or thistle (Scotland), reverse. Versions bearing the designs of a flax plant (Northern Ireland) and an oak tree (England) were introduced in 1986 and 1987, respectively. Royal maundy money (since the 18th century) is maintained with the issue of silver pieces of onepenny, twopence, threepence, and fourpence: the silver penny and groat thus survive.

Wales has had no coinage, except perhaps for the penny of the chieftain Howel Dda (909–950).

Scotland. Coinage began by following English usage in regard to types and weights: the earliest silver pennies were those of David I (1124–53) and copied Stephen's, though the use of profile portraits in the 13th and 14th centuries showed an interesting divergence. Gold nobles and silver groats were issued by David II in 1356–57 on the standard of Edward III. From Robert III onward the French or Flemish standard for gold was preferred, and during the 16th century, especially under James V and Mary, a strong continental influence on design was apparent in a series of gold coins of originality and frequent beauty. Silver coins had begun to show debasement of metal, and as early as James III copper small change—"black" farthings—had been introduced. The Scottish coinage of James VI (James I of England) marked a peak in range and variety: after the union of the crowns in 1603, Scots coinage decreased in quantity and ceased in 1707 after the union of the Scottish and English parliaments. Hitherto the value of Scottish coinage in relation to English had been 12:1. Under George VI a shilling with a Scottish reverse was first coined as part of the general British series.

Ireland. Irish currency from the 8th to the 10th century consisted mainly of Anglo-Saxon, French, Viking, and Arabic silver; in the later 10th and 11th centuries silver pennies of the Norse kings of Dublin imitated Anglo-Saxon and Scandinavian models. There were also thin silver bracteates copying Norman types. Anglo-Irish coinage proper began with silver pennies and halfpence of John (the only coins to bear his name, which did not appear on English coins). Dublin, Waterford, Cork, Limerick, and Trim were striking silver (increasingly base) from groat to farthing from the 13th to the 15th century. The "three crowns" coinage with the saltire cross (the Fitzgerald arms) beside the shield came in with Edward IV and was continued by Richard III and Henry VII. "Harp" groats were struck at Dublin under Henry VIII, followed by his much baser issues. Gold was never coined, but copper was introduced quite early. In Ireland, as in England, the English Civil War produced a number of siege pieces, notably the money of the Irish peers Inchiquin and Ormonde. James II for his Irish campaign issued his "gun-money" series of brass (made partly from melted down old cannon), to be redeemed in silver when he should regain the throne. In 1723 there was uproar in Ireland over the monopoly granted to the English entrepreneur William Wood to mint a debased Irish coinage, derisorily termed "Wood's halfpence." Under pressure from, among others, Jonathan Swift, the satirist, whose "Drapier's Letters" furiously attacked him, Wood revoked his patent in 1725 (see below *Coins of the United States*). Irish coinage was discontinued in 1822; from then on, Irish needs were served by English coinage. In 1928 the coinage of the Irish Free State (later the Republic of Ireland) was introduced, with, obverse, harp on all denominations, and reverses bearing a range of animal, bird, and fish designs. In February 1971 the coinage of the republic was decimalized.

Siege pieces

Isle of Man and Channel Islands. The Isle of Man first had its own coinage, in bronze, from 1709 to 1733 under the earls of Derby; this was continued, in 1758 only, for the earls of Athol. Regal coinage in bronze appeared intermittently from 1786 to 1839. The characteristic badge was the "three-legs," or triskelis, forming the spokes of a wheel. Since 1840, English issues have been current.

Jersey and Guernsey have had their own bronze coinage for well over a century, showing the shield of three leopards proper to the Duchy of Normandy. Variation of types has occurred since World War II, the end of which prompted also the special issue of the Jersey "liberation penny" to mark the end of the German occupation. The coinage was decimalized in February 1971.

Colonies and Commonwealth. British colonial issues, begun under Elizabeth I with silver for the East India Company, were extended in the 17th century. New England colonists struck the silver "pine tree" and "oak tree" money from 1652; Charles II had silver rupees coined at Bombay for the East India Company with the company's arms; silver and copper "hog money" (obverse, boar; reverse, ship) was issued for Bermuda; and James II struck tin coins for American plantations.

There were few official attempts to provide colonial coinages in the 18th century; thus, currency in the British West Indies was based on Spanish, Portuguese, and Brazilian gold and especially on Spanish silver dollars, normally cut and counterstamped. Spanish dollars were similarly used in the early 19th century at Sierra Leone. In the 19th century, however, colonial issues proper multiplied. That of the Ionian Islands, from 1819, was among the earliest. In Malta one-third farthings were issued by William IV and Victoria. Gibraltar had copper from 1842. Farther afield, token bronze had been coined for Nova Scotia and New Brunswick from 1823; a general coinage for Canada appeared in 1858. Ceylon's coinage began with bronze half- and quarter-farthings and silver three-halfpence from 1838. The private *raj* of Sarawak had coinage from 1841. Australian coinage of sovereigns started as early as 1855; its unit was changed to that of the dollar on Feb. 14, 1966. In Cape Colony little coinage was produced until the Boer republic of South Africa had been incorporated in the Union. Silver and bronze for Hong Kong began in 1863, and in closely succeeding years colonial issues were

started for Jamaica, Cyprus, Mauritius, Zanzibar, North Borneo, Honduras, and elsewhere.

20th-century issues

In the 20th century, coins of the colonies continued in general to show a crowned bust of the monarch; those of the self-governing Commonwealth powers exchanged a crowned for an uncrowned bust. New Zealand issues, with Maori designs prominent, began only in 1933. Indian and Pakistani coinages, each bilingual with English, grew out of the imperial Indian coinage, the British sovereign's head being replaced in India by pictorial designs and in Muslim Pakistan by calligraphic and symbolic devices.

Generally, Commonwealth and colonial coins alike have emphasized on their reverses either national symbols or national heraldic devices. Those U.K. dependencies that had not by February 1971 decimalized their currencies adopted the new decimal currency that the United Kingdom introduced at that time. The currencies of the many nations that achieved independence in the second half of the 20th century exhibited a variety of types, including portraits, traditional emblems, and renderings of indigenous flora and fauna. (C.H.V.S.)

COINS OF LATIN AMERICA

The colonial period. Spanish colonists carried to the New World the Castilian currency system, which had been regulated as to standard, weight, and size of the coins within a bimetallic pattern by the ordinances of Ferdinand and Isabella issued in Medina del Campo in 1497. The double base of the system consisted of the gold excelente (replaced in 1535 by the escudo) and the silver real. The coins of Spanish America were specifically: in gold, the escudo (3.38 grams), two-escudos, four-escudos, eight-escudos, or onza (the famous gold ounce), and the half-escudo, or escudito; in silver, the real (3.43 and 3.38 grams), the half-real and the quarter-real, or cuartillo, and the two-reales, four-reales, and eight-reales (this last known also as the duro, or peso fuerte). During the 16th century, for a brief period, a coin of three reales was minted in Mexico. Gold was not minted in a uniform manner until after the second half of the 17th century; until then Hispanic-American currency had been almost exclusively silver coinage. Copper was rarely minted in Spanish America.

The gold ounce

The hammered coinage of Spanish America frequently presents a relatively tidy appearance, being very nearly round and containing all the lettering and required symbols; but the press or mill type coinage is frequently of very poor appearance. These coins of rude mintage are called macuquinas (cob). In the 18th century, by ordinances of Philip V, the setting up of machinery for the minting of a perfectly round coinage, with milled and corded (ropelike) edge, became mandatory.

The type of the Hispanic-American coin was very characteristic: its most constant elements were the Pillars of Hercules and the motto *Plus Ultra,* plus the monarchy's coat of arms. In edge-milled coinage the same elements were employed in silver pieces, with the addition between the Pillars of an image of the two crowned hemispheres; this was called the moneda columnaria ("columnar coinage") and was minted until 1772. From that date, by ordinances of Charles III, silver coinage carried on the face a bust of the reigning monarch and on the reverse the coat of arms, a system already utilized in the gold pieces.

Hispanic-American colonial mints. At the beginning of the colonial period, stamped metal foundry pieces frequently substituted for scarce currency. In time, several mints were established, of which the Mexican (1535–1821) and the one at Potosí (1574–1825) were particularly important. Other minor ones, and their dates of operation, were those of Santo Domingo (1542 to the end of the 16th century and 1818 to 1821), Lima (1568 to 1570, 1575 to 1588, 1659 to 1660, and 1684 to 1824), Santa Fe de Bogotá (1626 to 1821), Guatemala (1731 to 1822), Santiago de Chile (1749 to 1817), Popayán (1732 and 1749 to 1822), and Cuzco (1698 and 1824). Coinage of any of these mints had uniform currency throughout the entire Spanish Empire, and the pieces had uniformity of type. They were distinguished by the symbol of the mint, carried on every coin. The following are some of the symbols used: Mexico, *M;* Potosí, *P* and, in the edge-milled coins, *PTSI* and *PTS* in monogram fashion; Lima, *P, L,* and, in the edge-milled coins, *LIMA* and *LIMAE* in monogram fashion; Santiago de Chile, *S;* Guatemala, *G* and *NG* (for Nueva Guatemala); Santa Fe de Bogotá, *NR* (for Nuevo Reino); Popayán, *P, PN,* and P^{N}; Santo Domingo, *SD;* Cuzco, C° and *CUZ.*

Spanish colonial types

Dissemination of Hispanic-American coinage. The larger silver and gold pieces, the eight-reales, or pesos fuertes, and the ounces, became in modern times the international currency par excellence. Their dissemination throughout the world was brought about by the uniformity of their standard and milling characteristics. In many countries they were counterstamped to adapt them to a local monetary system or to authorize their currency.

Emergency coinages in the era of independence. During the wars of independence, between 1810 and 1826, emergency mints were established in different parts of the continent, by the royalists as well as by the patriots. The coinages were almost always crudely designed, being in some instances merely foundry coinage. On other occasions the coins had merely fiduciary value—that is, no intrinsic value at all—as was the case with the numerous coinages of the Mexican patriot José María Morelos (1765–1815), who produced eight-real pieces in copper. Only in Mexico were there mints of any importance, situated in 10 different localities. The coinage situation became further complicated when the authorities of the opposing forces started counterstamping each other's coins in order to use them within their own camps.

The independent countries. The independent states that arose in Latin America after the revolutions of 1810 proceeded to mint new coins, retaining the bimetallic system established by Spain, with units in reales and escudos, except for copper fractionary units. After 1850, within a period of about 15 years, all the states adopted the decimal system, and the peso became the unit, though in several cases it took a special name. Within the second half of the 19th century, bimetallism was generally replaced by the gold standard, which in the 20th century was replaced in turn by fiduciary currency or paper money, coinages being limited to fractionary pieces or to "merchandise coins" (trade tokens with little inherent metal value).

Brazil. Coins minted in Spanish America circulated abundantly in Brazil from the 17th to the 19th century. They were given their official value in terms of the Portuguese reis, the corresponding amount being indicated by counterstamping. Hispanic-American eight-real pieces carried an overstamp that was at first of 480 reis, increasing until in edge-milled coins it amounted to 960 reis. By the 18th century, mints were established in Rio de Janeiro, Bahia, and Pernambuco, but joint circulation of both Hispanic-American and Portuguese coinages continued. Counterstamping ceased during the first decades of the 19th century, although Hispanic-American eight-real pieces and the equivalent coins of the independent Latin-American countries continued to be reminted with the value of 960 reis for some time. The Brazilian monetary unit that eventually became the milreis later became the cruzeiro, divided into 100 cents. (A. de A.-M.)

COINS OF THE UNITED STATES

The first coins struck in the North American Colonies were silver shillings, sixpences, and threepences, made by silversmiths John Hull and Robert Sanderson at a mint in Boston from 1652 to 1682, by order of the general court of Massachusetts Bay Colony. This mint dated its coins 1652 over the entire 30-year period to conceal the continuous mintage from British authorities in London.

Pre-Revolutionary coinage

With very few exceptions, the coins circulating in the Colonies until the Revolution were unauthorized private issues or old worn coppers no longer acceptable in England or Ireland. Silver was rare (consisting mainly of Spanish and Mexican dollars) and gold almost nonexistent. Copper was then a semiprecious metal, and in theory (though seldom in practice) 24 copper halfpence contained a shilling's worth of copper. Some of the Colonies, notably those in New England, repeatedly experimented with paper money, with disastrous results. Ostensibly to satisfy the colonists'

needs for metallic currency, but in reality for the benefit of owners of mines in Cornwall, the Royal Mint in 1688 issued tin farthings bearing the image of James II on horseback and the curious denomination of 1/24 of a Spanish real. The Rosa Americana pieces, struck by William Wood of Wolverhampton under royal patent dated July 12, 1722, received a disappointingly small circulation in New York and New England. Another coinage by Wood in 1722–24, intended for Ireland but rejected there because of scandalous circumstances surrounding his purchase of the royal patent, was shipped to the North American Colonies. Later these coins were supplemented by quantities of lightweight imitation halfpence, made principally in Birmingham, Eng. Alone among the Colonies, Virginia (because of a provision of its 1606 charter) had an official copper coinage executed at the Royal Mint in 1773. New Hampshire authorized William Moulton to make coppers in 1776, but the number was extremely small. The Continental Congress, colonial delegates of the incipient United States, uttered pewter dollars in the same year to provide moral support for its inflated paper currency. These bore a sundial, the word *Fugio* ("I flee"), the motto "Mind Your Business," and 13 links for the united colonies.

British copper tokens

The end of the Revolution in 1783 occasioned the manufacture and circulation of immense quantities of British copper tokens designed for the American trade. Between 1785 and 1789 the Republic of Vermont and the states of Connecticut, New Jersey, and Massachusetts awarded contracts to various individuals to strike copper coins, and Congress similarly licensed James Jarvis in 1787 to make cents of the same design as the 1776 dollars. All these ventures were failures, the authorized coins being driven out of circulation by British tokens, Birmingham halfpence, and the lightweight issues of "Machin's Mill" (a clandestine mint near Newburgh, N.Y.). The copper panic of 1789–90 followed, coppers of all kinds dropping to 72 to the shilling from their former 14 or 15.

Congressional efforts to establish a national mint had resulted in the issue of the historic 1783 Nova Constellatio silver patterns of 1,000, 500, and 100 units, from dies by the Englishman Benjamin Dudley, exemplifying the extraordinary Morris Plan, drawn up by Robert Morris, superintendent of finance, which reconciled the diverse colonial moneys of account. In 1786, however, Congress adopted instead the proposals of Thomas Jefferson for a decimal monetary system based on the dollar, and in 1792 the mint was finally built in Philadelphia, with David Rittenhouse as director. Jefferson tried vainly to hire as die engraver a Swiss, Jean Pierre Droz, who nevertheless furnished dies, hubs, and presses. Before the mint was quite ready, the first official American silver coin, the half dime, was struck in October 1792 in John Harper's cellar a short distance away, from dies by Robert Birch and Joseph Wright, who were also responsible for the regular cents and half cents of 1793. Silver followed in 1794 and gold in 1795, the engraver being Robert Scot.

Later American designers

Later designers of American coins included Gilbert Stuart (1796 silver), Titian Peale and Thomas Sully (the 1836 dollars engraved by Christian Gobrecht), Augustus Saint-Gaudens (1907–33 10- and 20-dollar gold pieces, called eagles and double eagles), Bela Lyon Pratt (1908–29 half eagles and quarter eagles), Victor Brenner (the Lincoln cent), James Earle Fraser (the buffalo nickel), A.A. Weinman and Hermon MacNeil (1916 silver), John Flannagan (1932 quarter dollar), Laura G. Fraser, and Chester Beach and Gutzon Borglum (various commemorative coins).

Figure of Liberty on a U.S. $20 gold piece designed for Pres. Theodore Roosevelt by Augustus Saint-Gaudens, 1907. The relief being too high, the coin proved unsuitable for circulation. In the American Numismatic Society, New York City. Diameter 34 mm.

The discovery of gold and silver in various regions and the difficulty of transporting large quantities of bullion through country menaced by Indians and bandits prompted the founding of both private and federal local mints. The Bechtlers of Rutherfordton, N.C., coined locally mined gold long before the government built a mint in Charlotte. The California gold rush stimulated coining by many bankers and assayers. Private coinage was legal so long as the coins contained full bullion weight and purity and imitated no official issues; Bechtler and Moffat gold (the latter coined at San Francisco) circulated at about par until the Civil War, while lightweight private gold took a discount. The California private mints mostly ceased operations when the San Francisco federal branch started, but those in the less accessible regions of Colorado continued long afterward, and as late as 1901 Joseph Lesher struck octagonal silver dollars in that state.

From 1851 to 1900 many brief experiments with odd denominations were tried, all of which proved superfluous. A law of 1873 discontinued the silver dollar until political pressure from mine owners forced through Congress an 1878 act requiring the mint to buy $2,000,000 to $4,000,000 worth of silver monthly and coin the entire amount into silver dollars. Coinage was discontinued in 1935. Millions of the silver dollars long remained stored in banks and treasury vaults, but eventually they became scarce; and in 1964 a new minting was authorized. Gold was recalled in 1934, but gold coins of numismatic interest may be retained in any quantity by "collectors of rare and unusual coin" (Presidential Order 6260). By an act of 1853 all silver coins except the dollar are fiduciary. The passing of 19th-century artistic canons has been reflected in American coin designs, which since 1909 have portrayed statesmen rather than personifications of liberty. All the above influences have combined to make the 20th-century American coinage system the simplest in use in any major nation. (W.H.Br.)

Recall of gold currency

COINS OF ASIA

Ancient Persia. *Achaemenids.* The ancient kingdoms of the Middle East—Egyptian, Sumerian, Babylonian, Assyrian, and Hittite—had no coined money. The use of coins reached Persia from the Lydian kingdom of Croesus and the Persian satrapies of Asia Minor. The first ruler of the Achaemenid dynasty to strike coins was probably Darius I (522–486 BC), as the Greek historian Herodotus suggests. The coins of the dynasty were the daric struck from gold of very pure quality and the siglos in silver; 20 sigloi (shekels) made a daric, which weighed 8.4 grams. The types of both coins were the same: obverse, the Persian king in a kneeling position holding a bow in his left hand and a spear in his right; reverse, only a rough irregular incuse caused in the striking. These roughly oval pieces were uninscribed and remained in issue unaltered in type until the fall of the empire. The issue of gold was the royal prerogative, but the conquered Greek and other cities and states were allowed to issue silver and copper, while a number of Persian satraps struck silver in their own names, producing some of the earliest and finest coin portraits. At the fall of the empire, various satraps struck silver coins of their own.

Daric and siglos types

Parthians. Alexander's coinage and that of the Seleucids were purely Greek in character. In the mid-3rd century BC the Parthians became a great power in Persia. They had an extensive but monotonous coinage in silver (tetradrachms and drachmas) and copper. The coins do not bear the name of the issuer but that of Arsaces, which was used as a dynastic title. Some of the coins are dated in the Seleucid era; on the later coins the Greek becomes corrupt and is often joined by an inscription in Persian. Some local dynasties (*e.g.*, of Persis and Characene), vassals of the Parthian kings, also struck coins.

Sāsānians. The Sāsānian coinage was very extensive in silver, and the early emperors also coined gold and copper, although rarely. The coin types throughout the dynasty are the same: on the obverse is a bust of the king with his name and titles, and on the reverse a fire altar, usually with two attendant priests. From about the 4th century AD, with a few earlier examples, the reverse legend gives the mint and the regnal year of issue. The standard of the gold coins is derived from that of the Roman solidi; the silver coins are drachmas following the Parthian standard and are remarkable for their broad, thin form, which was copied by the Arabs for their silver coins.

Islāmic coins of the West and of western and Central Asia. The conquering Muslims at first mimicked the coinage of their predecessors. In the western provinces they issued gold and copper pieces imitated from contemporary Byzantine coins, modifying the cross on the reverse of the latter somewhat to suit Muslim sensibilities. In the eastern provinces the Arab governors issued silver dirhams that were copies of late Sāsānian coins (mostly of those of Khosrow II) with the addition of short Arabic inscriptions on the margin and often the name of the Arab governor in Pahlavi; even the crude representation of the fire altar was retained. Toward the end of the 7th century, the fifth Umayyad caliph, ʿAbd al-Malik, instituted a coinage more in keeping with the principles of Islām. This "reformed coinage" was of gold (first issued in AD 698–699), silver (first issued in 696–697), and copper. The old coin, called dinar (from the Aramaic derivation of the Roman denarius aureus), derived its standard (4.25 grams) from the Byzantine solidus; the standard of the silver coin (dirham, from the name of the Sāsānian coin, which in its turn was derived from Greek drachma) was reduced to 2.92 grams, but it retained in its thin material and style some features of its Sāsānian predecessor; the name of the copper change, *fals,* comes from the Latin word *follis* ("money bag," by derivation a copper coin of low value). The reformed gold and silver coinage has no pictorial type, only skillfully arranged inscriptions, which are nonetheless of high historical value.

Reformed dinar and dirham types

The reformed dinar and dirham bear on the obverse the Muslim profession of faith—"There is no god but God: he has no associate"—and around it the marginal legend "In the name of God; this dinar (or dirham) was struck at . . . in the year . . . ." The reverse area has a quotation from Qurʾān CXII, "Say: He is Allah, the One! / Allah, the eternally Besought of all! / He begetteth not nor was begotten. / and there is none comparable unto Him." Around is Qurʾān IX, 33: "He it is who hath sent His messenger with the guidance and the Religion of Truth, that He may cause it to prevail over all religion, however much the idolators may be averse."

In the mid-8th century the ʿAbbāsids overthrew the Umayyad caliphate but at first made little change in the coinage. In time the caliph's name was added and, at the provincial mints, that of the local governor, and in the 9th century a second marginal inscription was added: "Allah's is the command in the former case and in the latter—and in that day believers will rejoice / In Allah's help to victory." (Qurʾān XXX, 4–5).

The ʿAbbāsid caliphate broke up in the 9th and 10th centuries, and the succeeding independent rulers regularly put their own names on the coins, although they retained that of the caliph of Baghdad, whose nominal authority was still recognized. Thus, in northern Africa and Egypt the Idrīsids, Aghlabids, Ṭūlūnids, and Ikhshīdids had their own coinage. From the eastern provinces there are the coins of the Ṭāhirids, Ṣaffārids (both in the 9th century), and the Būyids (10th–11th century). In Central Asia there was the extensive coinage of the Sāmānids, mainly in silver. In northern Africa and Egypt the extensive Fāṭimid currency in gold introduced a new type of dinar with legends arranged in three concentric circles. In the west the Umayyads of Spain issued a copious coinage from the mid-8th to the beginning of the 11th century, first in silver and later also in gold; their tradition was continued during the 11th century by the small local rulers of Spain who succeeded them and by the Almoravids, who united Morocco and Spain in one empire.

Islāmic gold coinage became one of the great currencies of the medieval world, and the dinar enjoyed great popularity on the western shores of the Mediterranean. It was referred to in Europe in earlier times under the name of *mancusus,* while the Almoravid dinar was known as *morabiti* (whence Spanish *maravedí*). The quarter dinars (known as taris) of the Fāṭimids, who ruled also in Sicily, were imitated in southern Italy and Sicily and by their Norman successors. Huge quantities of silver dirhams also reached eastern and northern Europe and especially (as a result of the fur trade) Scandinavia.

The Almohads, who succeeded the Almoravids in the 12th century, introduced a coinage that was new in both standard and form. Their fine gold dinars (2.3 grams) are among the most beautiful coins of the Muslim world; the dirham (1.5 grams) is square. The coinage of the Almohads survived also among their successors, well into the late Middle Ages, and was also widely current, and imitated, on the European shores of the Mediterranean.

In the east the successors of the Seljuqs (Artukids, Zangids, etc.), who, because of the scarcity of silver, issued large copper coins, introduced a striking innovation: they adopted types borrowed from ancient Greek and Roman, Sāsānian, and Byzantine sources. The Seljuqs of Asia Minor (12th–13th century) had silver coins showing a horseman with a mace over his shoulders, or a lion and sun. Farther east the Ghaznavids (10th–12th century), on their conquest of India, struck coins with Sanskrit inscriptions.

Mongol coinage

In the 13th century the Mongols swept through all Asia except India. The khans of the Golden Horde issued an extensive series of small silver coins (which influenced early Russian coinage). The Il-Khans of Persia struck large and handsome coins in all three metals. In the 14th century, Timur (Tamerlane) revived the power of the Mongols and struck silver and copper coins. His son Shahrukh introduced a new type of dirham, with, obverse, profession of the faith with the name of the first four caliphs on the margin and, on the reverse, his title.

Meanwhile, the new gold Venetian ducat spread in the East. It was used until the 18th century, and its standard (3.56 grams) was adopted for Islāmic coins.

Ottoman Empire. The original coinage of the Ottomans consisted of small silver coins (*akche,* called asper by Europeans). Gold coins were not struck before the end of the 15th century; before and after that century, foreign gold, mainly the Venetian ducat, was used. A notable Ottoman innovation was the *tughra,* an elaborate monogram formed of the sultan's name and titles, which occupies one side of the coin. Various European silver dollars also circulated extensively.

Later Persia, Afghanistan, and Turkistan. The earlier coins of the shahs of Persia were large, thin silver pieces of Central Asian style, but in the 18th century the coins became smaller and thicker, as in India. Legends were usually in rhyming couplets; gold was scarce until the 18th century. Cities issued copper with local emblems.

The emirs of Afghanistan, who became independent of Persia in the 18th century, struck gold and silver on the standard of the Mughal emperors, whose poetic inscriptions they also copied. Of the various smaller modern dynasties that ruled Central Asia until the Russian conquest, the emirs of Bukhara and of Khokand were notable for their extensive issues in gold. From the 19th century gradual westernization resulted in the adoption of European types.

India. *Ancient and early medieval.* India derived the idea of coinage from the Greek world via Iran. The earliest coins were weighed from pieces of stamped silver and were decorated with stylized depictions of animals and plants. These coins were soon augmented by copper ones, some made in the same way, others by casting. These pieces circulated over most of northern India during the 4th to 1st centuries BC. From the 1st century BC onward there were also copper coinages of numerous small states, tribes, and dynasties, which show increasing Greek influence. Their few silver coins were directly influenced by the hemidrachms of the Greek rulers of northwestern India of the 1st century BC.

Early in the 2nd century BC the Greeks of Bactria began

to invade India, and their coinage is remarkable for its fine series of portraits and for the number of names it records of rulers otherwise unknown. Prākrit legends began to appear alongside Greek and, as the Greek rulers were replaced by Central Asian invaders who copied their types, the Greek deities gradually gave place to local ones on the coins.

Kushān coinage

In the mid-1st century AD another group of Central Asian invaders, the Kushāns, founded a great empire in northwestern India; they left a wealth of gold and copper coins with legends in the Bactrian language, written in cursive Greek letters. Their coin types—of king on obverse and deity on reverse—became the general style of northern Indian coinage for the next 1,000 years. The type was continued by the kings of Kashmir to the 10th century and adopted, with modifications, by the great Gupta emperors in the 4th century. The Guptas struck an extensive gold coinage; among the more notable Gupta coins are those that commemorate Candra Gupta I's horse sacrifice or depict him as a lyrist.

In western India a dynasty of satraps of Persian origin had been ruling since the 1st century AD. Their extensive silver coinage is dated and therefore of unusual historical value. This kingdom was overthrown by the Guptas at the end of the 4th century, and they at once began to imitate this silver coinage locally. The Huns (Hephthalites), who destroyed the Gupta and other smaller states in northern India in the 6th century, left numerous coins, imitated from Sāsānian, Gupta, or Kushān prototypes. Copies of these continued to circulate in parts of northern India until the revival of various Hindu dynasties from the 10th century onward. A notable adaptation of a Hun design was the neat silver coinage of the Shahis of Gandhara of the "bull and horseman" type in the 9th and 10th centuries, extensively imitated by the Muslim conquerors of India and the contemporary minor Hindu dynasties. The other type favoured by the medieval Hindu dynasties for their gold coinage was that of a seated goddess—going back to a Gupta reverse—and an inscription with the king's name on the other side.

Gandharan silver

The coinages of southern India form a class by themselves. In the later centuries BC and early AD, the Andhras ruled a great kingdom in central southern India; they issued coins mainly of lead but also of copper and silver with types based on Greek or local northern Indian designs.

The later medieval dynasties of southern India struck coinages mainly of gold, the type of which is usually the badge of the dynasty; the Cheras of Malabar, for example, had an elephant, the Chalukyas of the Deccan a boar, the Pandyas a fish, and the cup-shaped pieces of the Kadambas a lotus. The Chola dynasty introduced under northern influence the type of a king standing, on obverse, and, on the reverse, the king seated, which spread through southern India and was taken to Ceylon by the Chola conquest and adopted locally. The great Hindu kingdom of Vijayanagar (Mysore) left a large series of small gold and copper coins with types of various deities.

Islāmic. The earliest Arab invaders had reached India in the 8th century and founded a dynasty in Sind, which left numerous very small silver coins of the Umayyad type. The coinage of the Ghūrid dynasty of northwest Afghanistan and its successors from the 12th century onward is varied and extensive, mainly gold and silver tangas (or rupees) of 10.76 grams. Gold was hardly issued at all in the 15th and 16th centuries, and for a time the coinage was mainly billon. Shēr Shāh of Sūr (1540–45), of northern India, issued a large silver currency of a type carrying the profession of the faith and names of the four caliphs, that was imitated by the Mughal successor of the Sūrs.

The coinages of Bābur and Humāyūn, the first two of the Mughal conquerors of India, are not extensive and are of Central Asian character. With the next two emperors, Akbar and Jahāngīr, is found a series unrivaled for variety and, within limitations, beauty—the gold coins of Jahāngīr are noble examples of Muslim calligraphy. In the 16th century the type that goes back to Shēr Shāh prevailed: the profession of the faith with the names of the first four caliphs and the emperor's titles on the other side; Aurangzeb replaced the confession of faith by the

Mughal types

Jaipur Nazarana silver rupee struck for presentation purposes by Isvari Singh (1743–60) in the name of the Mughal emperor 'Ālamgīr II. In the British Museum. Diameter 30 mm.

mint and date, and this remained the usual type until the end of the dynasty. The emperor's name is usually enshrined in a Persian couplet to the effect that the metal of the coins acquires added lustre from bearing the emperor's name. Nearly 50 such verses are found on Jahāngīr's coins. His reign is also remarkable for the series of coins bearing signs of the zodiac and for the set of portrait mohurs, one of which represents him holding a wine cup. From the beginning of the 18th century the coins become stereotyped, and the epigraphy loses its beauty. The European East India companies copied the native types from the local coinages and did not strike on European lines until the 19th century. A uniform coinage for territories under British administration was introduced in 1835. The right of native states to mint their own coinage was gradually curtailed by the British government. Since 1948, India, Pakistan, and Sri Lanka have had their own coinages. Bangladesh commenced independent coinage on Jan. 1, 1972.

Miscellaneous. Mention should also be made of the extensive Nepalese coinage in gold and silver with Sanskrit legends; the coinage of Tibet, related to that of Nepal; and the long series of octagonal gold and silver coins of Assam, struck until *c.* 1821.

China. Before coins were invented, cowrie shells were used as money in China. The earliest Chinese coins are small bronze hoes and knives, copies of the tools that previously had been used for barter. The knife coins (*tao*) were about six inches (15 centimetres) long and some bore inscriptions naming the issuer and giving the value. Hoe coins bore similar inscriptions. Both types circulated during the 4th and 3rd centuries BC. Round money with a hole in the centre was issued about the mid-3rd century, but it was not until 221 BC that the reforming emperor Shih huang-ti (221–210/209 BC) superseded all other currencies by the issue of round coins (*pan-liang*) of half an ounce. (There were 24 grains in the Chinese ounce, and in the Han period the ounce weighed 16 grams.) These *pan-liang* coins were continued by the Han dynasty. The official weight of this coin was gradually reduced until it was replaced in 118 BC by the emperor Wu-ti's five-grain (*chu*) piece, which remained the standard coin of China for the next three centuries; a break in the monotony of the regular coinage occurred in the archaistic innovations of the usurper Wang Mang (AD 9–23), who issued a series of token coins based on the *tao* and on square Japanese *pu* coins and various new round coins.

After the Han period (206 BC–AD 220), the standard coin underwent many modifications. The coin was issued in iron and lead, in six-grain and four-grain weights, and in token versions. Yet the ideal of the five-grain coin of Han survived until the rise of the T'ang dynasty, when the emperor Kao-tsu in 621 issued the Kai-yuan coin, which gave the coinage of all the Far East its form until the end of the 19th century—a round coin with a square hole and a four-character legend stating the function (*tong-bao,* which means "circulating treasure") and date of the coin. The Southern Sung dynasty (1127–1279) dated their coins on the reverse with regnal years, and the T'ang and Ming dynasties (618–907 and 1368–1644, respectively) put the mint name on the reverse, as did the Ch'ing dynasty (1644–1911/12), this last giving it in Manchu characters.

Kai-yuan coinage

Bronze token coin designed by Emperor Hui-tsung, Northern Sung dynasty, 1107. In the British Museum. Diameter 41 mm.

Paper money has been in use in China since the 9th century and was current almost to the exclusion of regular coins under certain Mongol emperors, such as Kublai Khan, whose paper money is described by Marco Polo. For more than 2,000 years the copper cash was the only official coinage of China; gold and silver were current by weight only, the latter in the form of ingots. As a result of the popularity of imported Spanish colonial and Mexican dollars, several attempts were made to institute a silver coinage based on the dollar in the 19th century; not until the very end of the 19th century were mints established to strike silver and copper coins of European style. Under the republic, coins were at once struck with the portraits of Sun Yat-sen and Pres. Yüan Shih-k'ai, and the various generals who fought for control of China issued their own coins. The currency of both the People's Republic of China and Taiwan is the yuan (dollar). The very extensive series of talismans, coinlike in shape but usually larger and in their legends and types reflecting popular Chinese religious thought, is noteworthy.

Japan. The art of coinage was borrowed from China by Japan, whose first bronze coins were issued in AD 708. To the mid-10th century, 12 different issues were made, each of a different reign. For the next 600 years, however, no government coins were issued, and grain and cloth were used as money. From the Middle Ages imported Chinese coins began to circulate along with locally minted imitations. In 1624 the copper *kwan-ei* was first issued and remained in vast variety the usual issue for more than two centuries. The *ei-raku* and *bun-kyū sen* of the 19th century were the only other regular copper coins. Unlike China, Japan has had a gold and silver coinage since the 16th century. The gold coins are large flat pieces in the shape of rectangles with rounded corners, the largest size being *ōban* and the smaller *koban*. Other gold pieces are the small rectangular pieces of one and two *bu* issued from time to time; round gold is rare and usually of provincial mints. Silver was originally in the form of stamped bars called long silver; these were supplemented by small lumps, also stamped, called bean silver. They were later augmented by issues of silver pieces in the same shape as the small rectangular gold coins.

The Tokyo mint

In 1869 a mint on European lines was established in Tokyo, and gold, silver (yen or dollars), and copper were regularly issued from it until World War II, when nickel and various alloys superseded the precious metals. After World War II the yen was retained as the unit of currency. The *e sen* of Japan are not coins but amulets.

Korea. The earliest coins found in Korea were Chinese knife coins of the 3rd century BC. The local production of coins did not begin until the 9th to 10th century AD, when copies of contemporary Chinese Kai-yuan coins were made. Coins with local inscriptions, still based on the Chinese model, were issued from the 12th century. Chinese-style coins continued to be used until Japanese and Russian influence led to the introduction of Western-style coinage in the late 19th century.

Vietnam, Kampuchea (Cambodia), Laos. Nam Viet (present-day Vietnam) began by imitating Chinese coins and had a regular bronze coinage of its own on the Chinese model from the 10th to the 19th century. Silver became common in the 19th century in the form of narrow oblong bars. Presentation pieces in gold, silver, and copper were created in a variety of designs bearing, for example, auspicious inscriptions and quotations from the Chinese Classics, in addition to the king's name. The native coinage continued until World War II but had largely been replaced by French colonial issues. After independence from France, Vietnam substantially retained the Western alphabet on its often very attractive coinage. Cambodia (Kampuchea) had its own coinage from the 15th century—curious uniface round pieces decorated with simple religious pictorial designs. Western-style coinage began to replace these from the mid-19th century. Separate coinages subsequently were in circulation in Cambodia and Laos, as they were in North and South Vietnam during the 1945–76 partition.

Burma and Thailand. The earliest coinages of Southeast Asia were issued in Burma and Thailand during the late 1st millennium BC. They were derived from Indian prototypes (examples of them have also been found in Cambodia and Vietnam). From as early as the 17th century Thailand struck gold and silver coins in the form of balls made by doubling in the ends of a short, thick bar of silver and bearing the stamp of the reigning monarch ("bullet" coins). After *c.* 1860 it had a coinage on European lines with issues in gold, silver, tin and copper, and later nickel. (J.Al./S.M.Sn./Ed.)

COINS OF AFRICA

The Aksumite kings, powerful rulers of a kingdom in northern Ethiopia from the 2nd to the 9th century AD, and Christian from the 4th century, issued small gold coins, with a little bronze and very rare silver, from the 3rd century onward; the initially Greek inscriptions were replaced ultimately by Amharic. Indigenous coinage lapsed in the 10th century, the country becoming dependent on imported currencies, of which the silver Maria Theresa thalers of Austria were conspicuous from the 18th century onward. National coinage was resumed by King Menelik II, emperor of Ethiopia (1889–1913) with silver coins called talaris and their fractions and subsidiary copper, showing the Lion of Judah reverse—an allusion to the tradition that Menelik I had been the son of King Solomon and the Queen of Sheba. Some gold came later, to be continued by Emperor Haile Selassie (1930–36), who coined also in nickel and bronze until the Italian occupation and after his restoration in 1941. A national coinage continued after he was deposed in 1974.

Ethiopia

North Africa. Elsewhere the 19th-century partition of Africa by colonial powers led to a great miscellany of currencies before decolonization and independence were achieved from the mid-20th century. Egypt, gaining independence from the Ottoman Empire in 1914, based its currency on the piastre, with Arabic inscriptions; some gold and silver multiples were produced. Under Fu'ād I (1922–36) and Farouk I (1936–52) the royal portrait was used. The subsequent republic, with its piastres of aluminum–bronze alloy accompanied by rare silver and even rarer gold, has often chosen types referring to national history (*e.g.*, the Great Sphinx, Ramses II, the Aswān High Dam).

The piastre became the unit of Libya, which, after a period as an Italian colony, briefly became a kingdom under Idris I (1951–69), with a fine portrait coinage, before the regime of Col. Muammar al-Qaddafi. The piastre was also the unit of the French protectorate of Tunisia until 1891, when a coinage of francs and centimes was introduced. Independence from France in 1956 brought Arabic inscriptions. The piastre was also adopted in 1956 as the unit of the new republic of The Sudan. In Morocco, however, which was an early 20th-century protectorate of France, the unit was the Arabic silver dirham, replaced in 1902 by the silver rial until the introduction of the franc in 1921.

Sub-Saharan Africa. Further south the various regional currencies grew out of the 19th-century European colo-

nization. Thus Ghana, before independence in 1957, had been the British colony of the Gold Coast, in which the British denominations of shilling and penny were traditionally used; special gold was coined to mark the declaration of a republic in 1960. Similar developments took place in the British colonies of East Africa and in the colonial territories of Northern and Southern Rhodesia (later independent as Zambia and Zimbabwe), Nyasaland (later Malawi), and Nigeria. The currency of Liberia (founded by former American black slaves) from the mid-19th century consisted mainly of copper or bronze, with an elephant displacing the head of Liberty, of U.S. type.

In South Africa, before the Union was established in 1910, the only coinage of note was that of the South African Republic. During South Africa's membership in the Commonwealth its currency was assimilated to that of Great Britain, but when South Africa left the Commonwealth in 1961 it established a new system based on the gold rand.

Coinage for the French colonies such as the Cameroons, French West Africa and Equatorial Africa, Madagascar, and French Togoland, showing the French cockerel or the head of "Marianne" (emblem of the spirit of the French Revolution), was in general more standardized than in the British colonies. The principal Portuguese colonies were Angola and Mozambique; the former used macutas (equal to 50 reis) of copper, followed by centavos and silver escudos, while copper reis were current in the latter, followed by escudos or centavos. In the Belgian Congo (Zaire since 1971), originally established as a free state by King Leopold II in 1885, currency was based on silver francs and copper centimes. (C.H.V.S.)

MEDALS AND MEDALLIC ART

Italy. The modern commemorative medal, in both form and content, was invented by the Italian painter Antonio Pisano (*c.* 1395–1455), called Pisanello. His first medal portrayed the Byzantine emperor John VIII Palaeologus and was made in 1438–39. His medals provided a portable portrait relief of the sitters, reproducible by casting in lead or bronze and small enough to be held in the hand. He placed a profile portrait on the obverse and an allegorical or pictorial scene on the reverse. This formula for the medal has lasted to the present day. Pisanello made medals of 16 sitters for the courts of Ferrara, Mantua, Milan, Naples, and Rimini. Major schools of medal making developed, particularly in Mantua, Florence, the Veneto, and Rome. The papal court had no local school but attracted medalists from all over Italy. Toward the end of the century the portrait effigy became bolder and more sculptural in the work of Niccolò Fiorentino and Sperandio of Mantua.

Pisanello

During the 16th century in Italy the cast medal continued in favour, and Leone Leoni (1509–90) of Milan and Pier Paolo Galeotti were its principal masters. Leoni was engraver at the papal mint in Rome from 1537 to 1540, Master of the Habsburg mint at Milan (1542–45, 1550–59), and court sculptor to Charles V. His most masterly cast medal is of Michelangelo (1561). He also produced struck portrait medals, like those of the Genoese statesman and admiral Andrea Doria. For the first time the struck medal became a common instrument of court propaganda, especially for the popes and for the ruling Medici family in Florence. Galeotti made more than 80 cast portrait medals, which rival the work of Leoni. Pastorino da Siena produced a long series of portraits of sitters of lesser rank, cast in lead without reverse type. The finest struck portraits were the work of the medalists Domenico di Polo and Domenico Poggini in Florence and Giovanni Bernardi, Alessandro Cesati, and Benvenuto Cellini at the papal court. Antonio Abondio drew his style from Leoni and from the charming Mannerist portrait medalists of Reggio nell'Emilia, particularly Alfonso Ruspagiari.

France. The earliest French medals were heraldic pieces struck in gold and silver, *c.* 1455, to commemorate the expulsion of the English. The first portrait medal was a struck gold presentation piece of Charles VIII and Anne of Britanny, made by local goldsmiths for a visit to Lyon in 1494. Italian medalists had worked in France and directly inspired the work of Jacques Gauvain and Jérôme Henry at Lyon. In 1550 mint officials were sent by Henry II to seek out and obtain German minting machinery, and in consequence numerous propaganda medals were produced, ascribed to the Huguenot goldsmith Étienne Delaune and to Claude de Héry. With the appointment in 1572 of the great Mannerist sculptor Germain Pilon (1535–90) by Charles IX to the new office of "contrôleur général des effigies," a new form of medal appeared. Pilon produced a superb series of large cast portrait plaques for members of the Valois dynasty and a series of struck medals for Henry III. For Henry IV the Danfrie family produced a series of struck medals. Jean Warin (1604–72) also made elegant cast pieces, and between 1636 and 1670 he held almost a monopoly of the production of struck pieces for the court. Guillaume Dupré (1574–1647) followed Pilon, charmed Henry IV with his portrait medals, and was appointed in 1604 "conducteur et contrôleur général" of the Paris Mint. Nicolas Briot (1579–1646), rival of Dupré, was a lesser master who was a skilled mechanic and engraver general at the Paris Mint from 1600. In 1625 he went to London, where he revived the English court's interest in the medal.

Germany and Austria. The free imperial cities under the Holy Roman Empire were important centres of patronage, and the sitters were proud burghers depicted in a realistic idiom. A few fine medals are ascribed to Albrecht Dürer, but the first professional medalist was Hans Schwarz of Augsburg, active in Germany and elsewhere between 1512 and 1532. Christoph Weiditz produced numerous Augsburg medals and with Schwarz showed the greatest sensitivity in capturing individual character in his portraits. Friedrich Hagenauer, active in Munich and in Augsburg (1527–32), produced more than 230 medals. In Nürnberg, Matthes Gebel (active 1525–54) and his follower Joachim Deschler (active 1540–69) were the principal medalists. Ludwig Neufahrer worked mainly in Nürnberg and the Austrian Habsburg domains, employed by Ferdinand I from 1545. The Italian expatriate medalist Abondio was called to Vienna and also appointed court medalist by Emperor Maximilian II in Prague in 1566.

The Netherlands. The famous medal of Erasmus of 1519, by Quentin Massys, made in Antwerp, is the grandest northern Renaissance medal, but it had no progeny. Of the regular professional medalists some, like Steven van Herwyck (*c.* 1530–67) and Jacob Jonghelinck (1530–1606), who worked in Italy for Leoni, adopted the Italian style, somewhat more idealized than the German. The war with Spain (1568–1648) stimulated the production of propaganda medals, which became a popular vehicle of nationalist sentiment. The Netherlands' tradition of silversmithing was also adapted to the medal. Highly skilled engraved portraits on thin plates of gold and silver were made. The masterpiece of this genre is a portrait of Elizabeth I of England's favourite, Robert Dudley, earl of Leicester, in 1586, engraved on gold by the Dutch Mannerist engraver and painter Hendrik Goltzius (1558–1617). Simon van de Passe produced similar work and went to London, where he created a series of Tudor and Stuart portraits.

Massys' Erasmus medal

The Baroque period. The large struck propaganda medal was issued widely in northern Europe in the 17th century. The Thirty Years' War and later the Dutch wars with France and England stimulated such issues. Sebastian Dadler (1586–1657) was employed by the courts of Saxony, Sweden, Poland, and the Holy Roman Empire to produce large struck medals on the political events of the time. The Swiss Johann Carl Hedlinger (1691–1771) was trained in Paris, became court medalist in Stockholm, and produced numerous historical medals on commission. His portraits are the most elegant and individualistic effigies of the 18th century. The European medal was dominated by the court style of Versailles. The grand propaganda series of the *Histoire métallique*, a series of medals struck to commemorate Louis XIV's reign, was envied and imitated throughout Europe, though the Dutch copied it in a manner calculated to ridicule the French. The technical excellence of the Paris Mint was also imitated. The first fully Baroque medal in England, on the Restoration of

The *Histoire métallique*

King Charles II in 1660, was made by the Paris-trained medalist John Roettier, in the full French court style.

Caspar Gottlieb Lauffer of Nürnberg from 1679 issued a large number of medals engraved by numerous artists and commemorating contemporary events. He eventually published a catalog, in 1742, entitled *Das Laufferische Medaillen-Cabinet.*

The cast medal continued to be made. In Italy, the Tuscan sculptor, scholar, courtier, and mint master Massimiliano Soldani-Benzi (1656–1740) revived the cast portrait medal in 1677 and founded a school with his pupils Antonio Selvi (1679–1753) and Lorenzo Maria Weber (1697–1774). The school lasted until the 1740s. In Rome, the few cast medals included works by Charles-Jean-François Chéron (1635–98) and by Gioacchino Francesco Travani (active 1634–75), after designs by the great Italian sculptor of the Baroque, Gian Lorenzo Bernini. The Dutch silversmiths invented chased medals made of shells of silver hammered into relief from the reverse (repoussé) and soldered to a rim, the work by Pieter van Abeele (1608–84) being particularly charming.

In England, Thomas and Abraham Simon produced cast portrait medals of great refinement in a northern European realistic tradition. The cast portrait plaque was revived by the Romantic sculptor Pierre-Jean David d'Angers (1789–1856) in his series of portraits forming a *Galérie des contemporaines,* begun in 1827. The Paris school of the late 18th century, especially the work of Benjamin Duvivier (1728–1819) for King Louis XVI, combined Rococo elegance with realism. Duvivier's work included commissions from the U.S. Congress. The Napoleonic regime ordered an elaborate *Histoire métallique.* The Duvivier era saw the introduction of steam-powered presses for coin and medal making, perfected by the English engineer Matthew Boulton at Birmingham in 1786, and the use of the reducing machine, which permitted the translation of a sculptor's large-scale relief model into a working die (see below *Techniques of production*). This invention was crucial to the development of a new Parisian school of the Art Nouveau, founded by Jules-Clément Chaplain (1839–1909) and Louis Oscar Roty (1846–1911).

The reducing machine

A rival and similar school developed in Vienna and spread in Hungary and Bohemia. Britain was touched by the missionary zeal for the Art Nouveau style shown by Alphonse Legros (1837–1911), and a few sculptors, most importantly Alfred Gilbert (1854–1934), took up medal making. Frank Bowcher (1864–1938) studied under Legros in Paris, where he produced both struck and cast medals. He became engraver at the Royal Mint, London. In the United States, Augustus Saint-Gaudens (1848–1907) produced admirable medals and portrait plaques in the same Art Nouveau style.

The German reaction to the power of the Parisian school produced a school of expressionist medalists, while in France the 1920s saw the beginning of the Art Deco medal. After World War II the artistic medal continued to show remarkable possibilities as a medium for portraiture. Wit, imagination, and experiments with form brought the medal to resemble the plaquette or ornamental tablet. The variety and originality can be seen through the biennial exhibitions of the Fédération Internationale de la Médaille. (J.G.P.)

TECHNIQUES OF PRODUCTION

The essential advantage of using metals for currency, apart from durability, is that they can be shaped by melting and casting. Casting, therefore, has always been an integral part of the coin manufacturing process. Indeed, in some instances, it has been the only part. In early China bronze was cast into the form of the hoes and knives originally used for payment, and up to the 19th century the objects called "cash," with their square central holes, were also cast. Similarly, the first Roman issues, aes grave (heavy bronze), were ponderous cast pieces, the heaviest actually corresponding in weight to the libra, the Roman pound. However, as soon as the state realized that it could make a profit from issuing coins by decreeing that their value in the market should be greater than the intrinsic value of their metal content, casting—so simple an operation—at once led to counterfeiting. Provided the mold was made from an official coin, there was no straightforward visual way of distinguishing true from false. For this reason, casting alone seems not to have been employed for precious metal currency.

Casting and counterfeiting

The prototype coinage of Greek Ionia on the west central coast of Anatolia in the 7th century BC consisted of pellets of electrum (a gold–silver alloy) made by pouring the molten metal onto the striated surface of an anvil, where, under the action of surface tension, they assumed a characteristic lenslike shape before solidification. The weight of the pellets was checked and confirmed for use by stamping them with a punch—a naillike piece of metal, probably of bronze or iron. The punch sometimes had a crudely fractured end surface (which, of course, would be unique), sometimes an engraved design (the latter produced on the punch by drilling with abrasive corundum dust, which ate away at the surface, as in the lapping process perfected over millennia for sealstones). A counterfeiter would have had great difficulty in simulating the exact form of the punch surface. Within a short time, the issuing authorities began putting their own validating punch marks on the pellets, thus producing coins as opposed to bullion. In India before the Mauryan Empire (*c.* 321–185 BC), currency consisted of small silver bars carrying as many as six marks; the boat-shaped silver emanating from Southeast Asia in the 19th century was also officially confirmed in this fashion.

Ancient minting. Most of the ancient dies that have survived are of bronze, although iron dies are thought to have been widely used also. Lower dies seem generally to have been disk-shaped so that they could sit in a recess on an anvil. In some instances the design may have been cut directly on the anvil. Engraving of the details was carried out using small steel tools (scorpers), or designs were drilled out using corundum dust. It is possible that major elements of the design were inserted by a "hub," or master punch stamped into the die, but not all scholars accept that this method was employed in antiquity.

Making dies

Blanks or planchets (*i.e.,* the small metal disks from which coins are made) seem first to have been cast by pouring the molten alloy from a crucible onto a flat surface, where they cooled into the characteristic lens shape. Later the metal was poured into molds, which sometimes consisted of two parts so that the metal was completely enclosed; traces of the "flash," or joining line, can still be seen on surviving coins. At Alexandria in the Ptolemaic period (323–30 BC), open molds were common; in these a sequence of disk-shaped impressions in the mold were connected by channels, and a number of blanks were thus obtained at one pouring. The upper surface of the blank, where slag and oxide accumulated, had to be "turned" off, or drilled out, presumably by a tool like a carpenter's bit, and the centre punch mark to accommodate the tool point is characteristic of Ptolemaic, Seleucid, and Greek imperial coins. Contemporary issues in India were often square in outline and were cut by chisel from metal sheets. Many Greek and Roman silver coins were plated; an envelope of silver sheet was soldered on a copper core, and it is by no means certain that all such specimens were the work of counterfeiters, since solid silver and plated coins sometimes appear to have been struck from the same dies. In the later Roman Empire (3rd century AD) silver issues were heavily debased with copper; prior to striking, the blanks were immersed in an acid bath that leached out the surface copper to expose more silver, giving a much more acceptable appearance to the coins when they were first issued.

Striking—the impression of the die designs on the blanks—was startlingly simple. The lower die, set in the anvil, was covered by the blank; the upper die, which was positioned above, was then given one or more hammer blows (see Figure 1). A two-pound hammer, wielded by one hand, could easily give a force at the die face of seven tons. To get the high relief typical of Greek issues, two or three blows were necessary, and often there is evidence of double-striking on the coins. However, by preheating the blank, as practiced in Athens in the 5th century BC, less force was required and die life was extended. Analysis

Striking

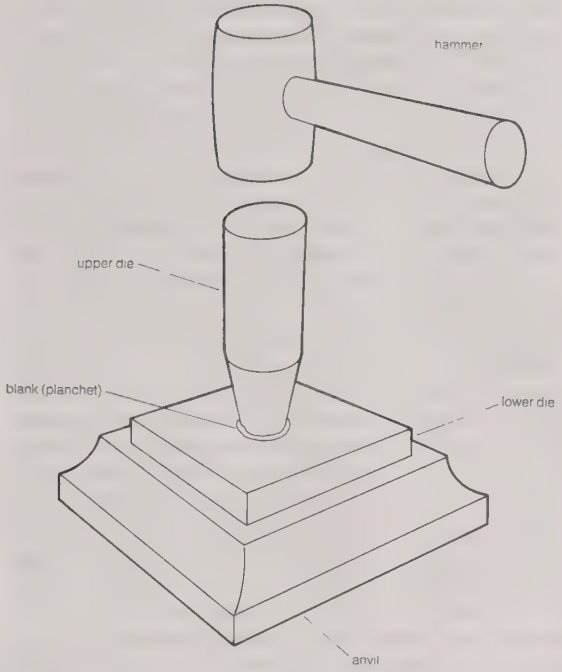

Figure 1: Striking, an ancient form of minting.

of the documentary evidence implies that one obverse (lower) die could produce upward of 20,000 coins, while 10,000 coins have been struck from a simulated bronze die without significant deterioration of the working surface. Receiving the hammer blows more directly, the reverse (upper) dies enjoyed about half the life of the obverse. Production rates varied. In small mints, operated by one man, a rate of 100 coins per hour has been shown to have been feasible. At important centres such as Rome or Antioch teams of four probably operated. An eyewitness account of a Persian mint in the 1870s describes how, with a hammerer, a die holder, a blank placer, and a coin remover, one piece could be struck about every two seconds.

Rate of production

Medieval minting. Alterations in the flan (the coin disk, a term deriving from the French *flatir,* "to beat flat") led to corresponding changes in the manufacture of dies. In about AD 220 the Sāsānian dynasty of Iran introduced the concept of thin flan coins, issues that were struck in relief on both sides. In order not to produce intolerable stresses in the dies, since the thinner the material the more force necessary to make it flow into the recesses of the die's design, the depth of relief on such coins was of necessity much shallower than with earlier currency. Such techniques spread by way of Byzantium to northern Europe, where the emperor Charlemagne (*c.* 742–814) struck thin flan deniers (small silver coins), or pennies, which became characteristic of both his own and neighbouring kingdoms.

The Franks and Saxons inherited an art that was formalistic rather than realistic, and this permitted their coin designs to be made up from a small number of standard elements that were reproducible using punches. It has been shown, for example, that the complete dies for all of the coin types of Edward the Confessor of England could be obtained from seven punches, giving individual wedges, crescents, pellets, and bars, each of which was independently struck to make up a legend and design. Consequently, a single workshop could supply the 70 or so contemporary English mints in a relatively short time. An experimental pair of dies took less than an hour to fabricate. Of course, many European dies were produced by a combination of punching and engraving, while engraving alone was typical of early Islāmic and contemporary Oriental dies. With the advent of larger denominations, such as the gros tournois (based on the weight standard of Tours, in France) in the 13th century, more florid designs came to be preferred, but the elements of the royal crown, for example, or the letters of the legend were still punched into the dies. To judge from surviving specimens, both upper and lower dies (trussells and piles) were by then produced from wrought iron. While the upper die retained the cylindrical shape of antiquity, the lower die was tanged (having protrusions added) so that it could be wedged into a wooden block.

Design elements

The thin silver sheet required for the new coins needed to be beaten out from its cast state, and this in turn necessitated annealing (strengthening by slow cooling) to prevent cracking. By the 10th century, squares of sheet, somewhat larger than the eventual penny, were being struck between square dies and then separated by a circular cutter. A few imitative coins on square flans are known from Scandinavia, while die identical coins have exactly matching edge irregularities, proving use of the same cutter. With the introduction of the gros tournois, the blanks were cut roughly circular with shears, then gripped by special tongs in rouleaux (columnar rolls) of a dozen or more, and finally hammered into circularity on a flat anvil. Alternatively, the silver was cast into thin rods of rectangular section; pieces of the correct length (and hence weight) were next cut from the rod by chisel and then, with several annealings, were beaten to the appropriate thickness, before being rounded and struck by a die. Blanching (cleaning) of the blanks by an acid dip was necessary before striking to produce an acceptable surface if oxidation had occurred during annealing.

Blanching

Striking was carried out in much the same way as during antiquity, although contemporary illustrations indicate that only one operator, not a team, was employed. Twelfth-century Byzantine coins were often cup shaped. A full impression of the curved dies could not easily be obtained by one blow; hence there evolved a method of striking one half of the coin with a slightly inclined upper die, which was then rocked over to the other side for a second blow. Bracteates, issues of foil thickness, were common in 12th-century Germany. To make these, a single die was used to strike a column of several blanks resting on a piece of leather, so that the reverse of each was the incuse (hollowed impression) of the obverse. Die life in general was higher than during antiquity, and documentary evidence for 13th-century English pence indicates perhaps 30,000 coins per obverse. There is no evidence for production rates.

Early modern minting. The increase of mining activity in central Europe during the 15th century gave a great impetus to the development of modern minting processes. The dies themselves were still made by punches, but these, in turn, had become much more sophisticated, often embodying a complete portrait of the monarch. Their general shape depended on the striking process employed, but the material used was a steel that could be hardened by carburizing (putting iron in a bed of carbon in a sealed air-tight box, and thence into a furnace, where the carbon diffused into the outer layers) after the designs had been punched in, or sunk.

The metal for the coins was cast as ingots, a typical size being $\frac{1}{2} \times 1 \times 20$ inches. These were then passed between steel rollers, powered by a water mill or horse gin (a mechanism that translated horsepower into rotational energy), to reduce the thickness. Several passes and annealings were necessary to obtain the correct thickness. The blanks, particularly for the larger crown-sized coins being introduced, continued to be roughly cut with shears from the rolled fillet (metal strip), so that, as previously, they could easily be adjusted for weight before being rounded in rouleaux. In some cases, however, they were punched by a machine from the fillet to a fixed diameter, so that the thickness was critical for controlling weight. To protect against clipping, during the next century a security edge was sometimes rolled onto the blank; this might consist of an inscription or a serrated or milled edge.

Security edging

Hand-operated screw presses were developed for stamping the designs on the blanks; although the blanks originally were centred on the lower die by eye, it soon became clear that a locating collar would prevent off-centre striking. Such a method was used by Benvenuto Cellini, who struck coins for Italian princes in the first half of the 16th century, and it was then introduced first to Paris and then to London in the 1550s.

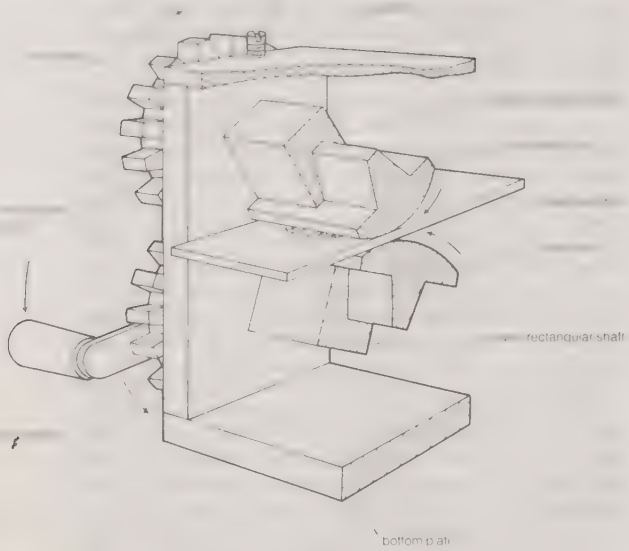

Figure 2: The *Taschenwerke* minting machine.

The roller press

At the same time the roller press was under development in Germany. Initially, the die designs were engraved or punched into the curved surfaces of two rollers that were geared together so that the whole fillet (rather than single blanks) could be fed between them and emerge impressed. This method was advantageous in requiring less power: only part of the blank was being deformed at any one time, and so, as compared with the screw press, the stresses on the machine were reduced. Because of imperfections, the fillet and the finished coins as punched out were markedly curved, and the coins required flattening (planishing) by light tapping with a smooth-faced hammer.

The difficulty of taking out the complete rollers from such a press led to an ingenious variation—the *Taschenwerke* (see Figure 2). In this machine the rollers were replaced by rectangular shafts pierced in the middle to take a pair of dies with tapered extensions (tangs). The axis of the upper shaft could be raised or lowered a short distance to accommodate variations in the dies or differing coin thicknesses. Such machines continued to be used in Germany into the 18th century.

The rocker press represents another variation. The bottom roller (actually a quadrant insert, as in the *Taschenwerke*) remained stationary; the axis of the upper roller rotated about this lower axis as a small circle around a larger, so that the upper die face rolled over a stationary fillet that had been positioned over the lower die. One such mechanism, now in the British Museum, produced minor copper coins in Spain soon after 1600.

The fly press

The prolific Jean Warin, one of the great engravers, finally established the use of the fly press, a variation on the screw press in which the helix angle of the screw was much increased. The rotational arms ended in heavy weights that were swung with great velocity by two operators (working for only 20 minutes in each hour), and the elasticity of the system caused a rebound of the arm to its original position after the coin had been struck. Again, with a team of moneyers, a rate of production of a coin every second or so could be achieved. In some Russian mints of about 1800 a guided dropping weight functioned in much the same way, regaining its original position partly by rebounding and partly by operators pulling on return ropes running over pulleys.

Contemporary mints. In the 1770s the steam engines of Matthew Boulton and the Scottish inventor James Watt made available new sources of power that were soon adapted to the coining process. Initially used to strike commercial tokens, these methods were eventually taken up by the Royal Mint in London. Experiments produced new steels that could cope with the much higher stresses involved, while a French invention, the pantograph, or reducing machine, permitted the manufacture of a standardized design for every denomination, all being reproduced identically but to differing scales.

Modern die manufacture

In modern minting, the sequence of die manufacture is as follows. A plaster model of the proposed design, about one foot (0.3 metre) in diameter, is received from the artist and a mold is made; from this is obtained an electrotype copy in nickel and copper. Mounted in the reducing machine, the copy permits the cutting of the design to the appropriate coin size in a block of steel, the master punch, which has features in relief, as on the eventual coin. The master is then used to punch-in, or sink, a matrix; this raises a working punch, which is used to sink a working die. Imperfections at any stage are removed by hand tooling and, for best results, the surface of the working die is highly polished before it is sunk.

The U.S. Mint

The production of blanks (called planchets in the United States) is highly automated. At the U.S. Mint in Philadelphia, for example, the incoming metal is assayed to ensure that it is of the correct specification. After being sheared into small pieces, the metal, together with the waste clippings (scissel) from previous blanking operations, is conveyed to a computer-controlled weighing section, where a charging bucket is filled with the correct proportions of each constituent of the required alloy; the metal then goes into a 15,000-pound-capacity electric induction melting furnace. During the melting, deoxidation additives are introduced, and the furnace is then tilted to pour the metal into a water-cooled, semicontinuous casting machine mold with a movable bottom. The resulting vertical ingot, with dimensions of 16 inches by 6 inches by 18 feet and a weight of 6,600 pounds, is set on a roller conveyer in a horizontal position preparatory to being cut by a rotary saw into two equal lengths. The bars are next raised in temperature in a high-frequency induction coil so that they can be hot-rolled. After nine passes the thickness of the bars is reduced to less than one-half inch, and the length is extended to approximately 115 feet. Quenching with water is followed by skim milling in order to remove the oxide layer on the top and the bottom surfaces. The coils of strip metal are next cold-rolled, reducing the thickness to about one-tenth of an inch. The ends of the individual coils are then trimmed and welded together, giving a large coil weighing some 4½ tons. Finally, the coil is rolled under tension in a finishing mill, where the thickness is controlled by sensors.

The blanking presses are typically high speed, punching out from the coils as many as 21 planchets per stroke at 100 or more strokes per minute, the scissel being returned to the melting pot. For coins of small denomination the planchets are then fed into an annealing furnace, quenched with water, cleaned with acid, washed, and dried. The subsequent operation is edge-up setting, the partial formation of a protective rim by forcing the blank into too small a hole. The planchets then proceed to the coining presses, many of which are adapted to cope with four coins at one blow. The spread of the metal under the force of the die is confined by a collar, and the radial recovery of the metal as the load is removed prevents its adherence to the collar, as the latter is retracted below die level. The struck coins are taken to a checking point, after which they are counted and bagged, ready for distribution. Die life is upwards of 200,000 coins.

Edge-up setting

The Royal Mint

The procedures at the United Kingdom's Royal Mint, at Llantrisant, Wales, are analogous. There, however, the ingots are cast continuously, not in discrete lengths, and they are subsequently sawed for the rolling operations. The edge-up setting is sometimes combined with the impression of a channeled security edge of the type found on Indian issues. To assist metal flow during striking, the washing and lubricating of the blanks are combined. The production of seven-sided coins (20- and 50-pence denominations) from circular blanks indicates the extent of the flow of the blank metal within the collar; the striking presses are capable of 600 strokes per minute. The counting and bagging operation is performed by robots. An experiment in obtaining the correct weight of gold issues, where the "remedy," or tolerance (permitted range of variation in the standard), is very limited, showed that when the blanks were punched from fillets that were one-third

inch thick and then pressed out to the normal thickness of one-tenth of an inch, the same error in initial thickness had less eventual effect on the weight of a one-third-inch blank than on a one-tenth-inch blank. In this experiment the same solution to obtaining correct weight was applied as in the medieval period, when the use of easily measurable lengths of thin silver rods gave the correct weight per penny. Collective Behaviour

Collective behaviour is a sociological term that refers to the ways in which people behave together in crowds, panics, fads, fashions, crazes, publics, cults, and followings as well as more organized phenomena, such as reform and revolutionary social movements. Because it emphasizes groups, the study of collective behaviour is different from the study of individual behaviour, although inquiries into the motivations and attitudes of the individuals in these groupings are often carried out. Collective behaviour resembles organized group behaviour in that it consists of people acting together; but it is more spontaneous—and consequently more volatile and less predictable—than is behaviour in groups that have well-established rules and traditions specifying their purposes, membership, leadership, and method of operation.

The U.S. sociologist Robert E. Park, who coined the term collective behaviour, defined it as "the behavior of individuals under the influence of an impulse that is common and collective, an impulse, in other words, that is the result of social interaction." He emphasized that participants in crowds, fads, or other forms of collective behaviour share an attitude or behave alike, not because of an established rule or the force of authority, and not because as individuals they have the same attitudes, but because of a distinctive group process.

The absence of formal rules by which to distinguish between members and outsiders, to identify leaders, to establish the aims of the collectivity, to set acceptable limits of behaviour for members, and to specify how collective decisions are to be made accounts for the volatility of collective behaviour. The leader of a mob can become the object of the mob's hatred in a matter of minutes; a fashion leader can suddenly become passé.

Although agreeing that collective behaviour does not generally adhere to everyday rules, some investigators emphasize the emergence of rules and patterns within the collectivity that are related to the surrounding social structure. The U.S. psychologist Ralph H. Turner and the U.S. sociologist Lewis M. Killian define collective behaviour on the basis of "the spontaneous development of norms and organization which contradict or reinterpret the norms and organization of society." Somewhat similar is the U.S. sociologist Neil J. Smelser's definition: "mobilization on the basis of a belief which redefines social action." The distinctive belief—which is a generalized conception of events and of the members' relationships to them—supplies the basis for the development of a distinctive and stable organization within the collectivity. But Smelser's definition points attention, in a way that other definitions do not, toward the unique manner in which members perceive reality; without such a view a group of people would not be engaged in collective behaviour.

The U.S. sociologist Herbert Blumer determined a desire for social change in collective behaviour, as expressed in his definition: "a collective enterprise to establish a new order of life." This definition, however, excludes many of the temporary escapes from conventional life through revelry and orgies, punitive actions such as lynchings, and panics, which are not oriented to any kind of reconstruction of social life or society. Most students of collective behaviour, however, would not restrict the field so severely.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* Part Five, Division II, especially Section 521.

This article is divided into the following sections:

Elementary forms of collective behaviour

Regardless of where or how collective behaviour develops, it requires some kind of preparation. In organized groups there are rituals, such as personal introductions, the toastmaster's humour, and group singing, to facilitate the transition from individual action to group interaction. People may act together efficiently if they have been prepared for a pattern of behaviour such as a fire drill, but the result is organized rather than collective behaviour. Lacking organization, people must first become sensitized to and begin to communicate with one another. These processes of sensitization and communication have been called elementary collective behaviour. Three important elementary forms are milling, rumour, and social unrest.

MILLING

Prior to most instances of collective behaviour there is a period during which people move about in a somewhat agitated but aimless way. Early students of crowd behaviour, struck by the resemblance to the milling of cattle before a stampede, gave this form of human activity its name. Its characteristic physical restlessness can be seen in an audience waiting for a late-starting program to begin or among citizens who have just received word of an assassination attempt. In the former case people scuffle their feet, leave their seats and walk about, and sometimes join spontaneously in rhythmic behaviour, such as foot stamping. In the latter case people discontinue routine activities and talk with neighbours, friends, and strangers. In most situations milling also means looking for clues to others'

feelings, such as sweating, nervousness, and changes in tone of voice.

Effects of milling

Human milling has at least four important effects. First, it sensitizes people to one another. In this sense milling focuses people's attention on the collectivity and on a subject or problem. Second, milling tends to produce a common mood among the interacting individuals. Where some might react with sorrow, others with anger, and still others with partisan delight or indifference, milling helps to diffuse a single mood within a group. Third, milling develops a common image or interpretation of the situation. The milling throng decides whether the Western tourist taking pictures of a marketplace in the native quarter of an Asian city is harmless or an affront to native dignity; whether the police in an American city are simply arresting a drunken driver or harassing an oppressed minority. Finally, milling sets in motion the process of redefining the rules that govern behaviour. The milling of an audience is usually the signal that customary rules of courtesy toward performers and speakers are no longer applicable and that different forms of behaviour may be expected.

RUMOUR

Rumour-creating situations. Rumour abounds under certain circumstances. The U.S. psychologists Gordon W. Allport and Leo Postman offered the generalization that rumour intensity is high when both the interest in an event and its ambiguity are great. The U.S. sociologist Tamotsu Shibutani agreed, contending that rumour abounds when the demand for news is greater than is the supply provided through institutional channels.

At least two conditions must be added to interest and ambiguity as prerequisites for rumour. First, rumour abounds when a group of people share the need to act but are reluctant to do so until the situation can be better defined. Second, rumour abounds only when the situation requires that in some essential respect the members of the group act in concert rather than individually.

Conditions encouraging rumour

There are three major kinds of situations in which these four conditions are commonly met and rumour is rampant. First, in a social order in which information is, or is believed to be, strictly controlled by authorities, rumour is intense. When control over news is a continuing (rather than temporary) condition, rumour becomes regularized as an essential aspect of daily life. The so-called grapevines created by these conditions are regularly utilized by totalitarian regimes, military organizations, and subordinated ethnic groups, races, and social classes.

Second, rumour spreads when events threaten the understandings upon which normal life is based. A major disaster or scandal presents such a challenge. Any change in the regular accommodations between potentially conflicting or competing groups in society similarly calls into question routine patterns of conduct. The suggestion that management may enforce factory rules more strictly, for example, or the suggestion that a college faculty may stiffen or relax degree requirements, immediately provokes a siege of rumour.

Third, rumour springs up when a strong, shared incentive to act is blocked in some way, even by merely the lack of an occasion for action. During states of boredom, rumour capitalizes on minor events, magnifying them into occasions for exciting collective action.

The transmission of rumour. Rumour spreads most rapidly along preexisting social networks: among friends, associates, and peers rather than among persons of unequal standing. The messenger who first relates a rumour earns prestige by doing so. Moreover, any specific rumour tends to spread most rapidly when it first enters a group, and to reach persons faster who have responsibilities and interests connected with the event.

The credibility factor

It is frequently assumed—incorrectly—that people transmit rumours only when they believe them and that discrediting a rumour will stop its spread. Other evidence suggests that people pass on rumours whether they believe them or not and that the likelihood of belief increases with their repeated hearing. This latter pattern is understandable if rumour is seen as a seeking, rather than a believing, process, in which every idea, no matter how invalid, provides a way of comprehending a strange or troublesome event. But since the group finds it urgent to reach a common understanding, pressure toward acceptance of a favoured version grows as the rumour process expands. Eventually, there is a sorting out of accounts and an insistence that everyone agree to a consensual account, which then serves as a basis for collective action.

Stages of rumour transmission. There is evidence that rumour follows a typical course. Evidence suggests that the rumour process eliminates the most improbable and unreliable accounts and achieves a high degree of veracity when (1) there is considerable recirculation of rumour and (2) there is a fairly well-organized grapevine. When rumour is recirculated the opportunity to compare versions with different groups of people acts as a brake on exaggeration and rubs off the idiosyncratic aspects of the story. With an established grapevine, the source of rumours can often be checked, and individuals who are known to have inside information are regularly consulted for verification.

In both early and late stages, rumour content changes with successive retelling in the direction of the understandable and familiar and in the direction of supporting the actions that the group is starting to take. The former is called assimilation by Allport and Postman and is illustrated by the tendency to make rumour details consistent with prejudice. The latter trend indicates that a group is inclined to support those beliefs that supply justification for some course of action toward which they are already predisposed.

SOCIAL UNREST

The general condition of the community in which milling is both frequent and widespread and in which rumour is recurrent is the crucible in which the more highly organized forms of collective behaviour develop. This condition, known as social unrest, can lead to outbursts of violence. The American urban black uprisings of the 1960s were preceded and accompanied by social unrest in the form of a rise in tensions in black communities throughout the country; the Russian Revolution was preceded by several years of constant unrest and turmoil, involving random assassinations, strikes, and riots.

Characteristics of social unrest

There are several distinguishing characteristics to social unrest. First, there is a general impairment of collective life routines. People find it difficult to concentrate on their work or even to adhere to rules in playing games. Any occasion to abandon routines is welcomed. Second, people are hyperreactive. The magnitude of the response is out of proportion to the usual meaning of any stimulating incident. A small police provocation elicits a major outcry of police brutality; a trivial success is the occasion for large-scale celebration. Milling and rumour abound because incidents that would normally pass with little notice become occasions for both. Third, social unrest is marked by contagiousness. When restlessness is strictly individual, one person's restlessness merely annoys another. But when restlessness becomes a shared experience, people are highly suggestible to one another. Questioning and exploring alternative courses of action are reduced to a minimum. Fourth, social unrest is not specific with respect to grievances or activities. When there is social unrest in a school, students complain of both restrictions on their behaviour and the lack of clearly defined rules; they find fault both with school administrators and with their fellow students. Finally, social unrest is perhaps the most volatile of collective states. Unlike rumour or milling, it does not remain focused on an issue or problem. Unlike crowd behaviour or fads, it has not yet been channeled into one main direction. Although social unrest may eventually die down without any serious aftermath, it is a condition in which people can be easily aroused.

Major forms of collective behaviour

RESPONSES TO DISASTER

A disaster-stricken community affords a prototypical situation for collective behaviour. The lives of persons are disrupted indiscriminately by a tornado, flood, or earthquake, and coping with the resulting destruction and dis-

order is beyond the capacity of conventional institutions. Of perhaps greatest importance, the assumption of a reasonably stable and predictable reality is undermined.

Common misconceptions. A number of common assumptions about behaviour under stress have been dispelled by research on responses to disaster. First, panic is rare. The quite specific conditions under which panic occurs is described below, but stoic, unbelieving, or even resigned reactions are more common than panic. Second, scapegoating is not the rule. Some investigations have suggested an almost unnatural avoidance of singling out villains and placing blame. Within the disaster community the establishment of solidarity is a concern that dampens scapegoating, at least until the immediate emergency is past. Third, there is much less looting and vandalism than is popularly supposed. Even among persons who converge from outside the community there is more petty pilfering for souvenirs than serious crime. Fourth, initially an altruistic selflessness is more prevalent than self-pity and self-serving activity. Frequently noted are dramatic instances of persons who have suffered injury or property damage themselves devoting their time to helping others in no greater need. Fifth, the disruption of established organizations and customary behaviour does not lead primarily to innovation and the exercise of freedom from old restraints. Instead, people more frequently cling to the familiar and seek reinstatement of the old.

The disaster cycle. Collective behaviour in disaster follows a characteristic cycle, from first warning to community rehabilitation.

Warning period. Although individuals read widely different meanings into disaster warnings, the striking feature of this initial stage is the slowness to believe and the reluctance to act upon warnings. People often remain in their houses in spite of imminent flooding and remain on familiar low ground in the face of tidal wave warnings. The surface calm that each person seeks to maintain in the presence of others can lead to collective self-deception and the inhibition of tendencies toward flight.

Slow reaction time

Impact and stocktaking period. In disasters such as floods and some hurricanes there is a distinctly long period of impact, which can be separated from a subsequent period of stocktaking or immobility. In earthquakes and explosions, on the other hand, the impact is so brief that the periods can hardly be separated. The combined period of impact and stocktaking is marked initially by a fragmentation of human relations, as each individual is separated from others and from his customary moorings; it is then marked by a resurgence of interpersonal warmth that transcends customary social barriers within the disaster community.

Rescue period. Just as initial fragmentation is followed by unnatural solidarity, stunned immobility gives way to a frenzy of activity in the rescue stage. Although activity is often inefficient, the task of rescuing persons who are trapped and of getting the injured to first-aid facilities is usually accomplished fairly expeditiously, often before outside help arrives. This is the period in which altruism becomes the norm, and old rivalries and conflicts are suspended. Many business concerns adopt an uneconomic generosity, and some individuals disregard their personal welfare. The imperious demand to "do something" at once creates an urgent demand for leadership. People turn first to established community leaders, and, when they are equal to the demands, such figures as police and fire officials, school principals, and mass-media personages are quickly accepted as leaders. Frequently these public figures are as bewildered and distracted as everyone else in the community and are soon abandoned in the restless search for leadership. The leaders then are found among persons who have the specific skills and tools required for the rescue efforts of the moment. Often these are people who do not normally exercise community leadership.

Prevalence of selfless aid

Rebuilding or "brickbat" period. The buoyed-up state of the disaster community can last only a short time. Tasks that call for intense effort within a brief time span are completed, and the slow and discouraging work of rebuilding confronts the community. Because the old community cleavages begin to reappear, and because tensions created and repressed during the rescue phase are now released, this period has been called the brickbat stage. The most notable characteristic of this period is the tendency to reinstitute the old community—to rebuild homes on old foundations, to reinstate old forms of organization. In spite of criticism against the ineptitude of established authorities, and in spite of evidence that building locations and methods are vulnerable to the elements, it requires strong leadership to guide the community toward innovation that makes use of what can be learned from the disaster experience.

COLLECTIVE OBSESSIONS

Characteristics of collective obsessions

The various kinds of collective obsession—fads, hysterias, and the like—have three main features in common. (1) The most conspicuous sign is a remarkable increase in the frequency and intensity with which people engage in a specific kind of behaviour or assert a belief. There was an "epidemic" of flying-saucer sightings; children in every residential neighbourhood in the United States played on skateboards; there was a sudden rush to buy Florida land. (2) The behaviour—or the abandon with which it is indulged—is ridiculous, irrational, or evil in the eyes of persons who are not themselves caught up in the obsession. In the case of recreational fads, such as skateboarding, nonfaddists are amazed at the tendency to drop all other activities in order to concentrate on the fad; the hundreds of incidents in which swastikas were daubed on synagogues during a few weeks in 1959 and 1960 in the United States, West Germany, and other countries shocked the sensibilities of a world that remembered the Nazi persecution of the Jews. (3) After it has reached a peak, the behaviour drops off abruptly and is followed by a counterobsession. To engage in the fad behaviour after the fad is over is to be subjected to ridicule; after the speculative land boom declines, there is a mad rush to sell property at whatever price it will bring. The following discussion covers five types of collective obsession: fads, hysterical contagion, deviant epidemic, fashion, and crazes.

Fads. It is tempting to explain fads on the basis of a single motive such as prestige. Prestige is gained by being among the first and most adept at a skill that everyone else covets. That the skill fails as a source of prestige when it is no longer scarce is an important explanation for the abrupt end of a fad. But motives are complex and varied. The exhilaration of joining a band of devotees in an intense preoccupation and the joy of mastering the novel are not to be discounted.

An examination of fads in such enterprises as scientific research and recreation sheds light on the fundamental dynamics of all kinds of fads. First, the scientific fad begins with a new idea or a rediscovered idea—though not just any new idea will set off a fad. The new idea must be a "key invention," one that opens up the possibility for a wide range of minor innovations. Discovery of a potent new drug, for example, is followed by a rush to test the drug in all kinds of situations. Similarly, recreation and style faddists do not merely copy a pattern; they try out a variety of novel uses and variations on the basic pattern. The Hula-Hoop was an ideal fad because each child could develop his own particular variation in spinning the hoop.

Second, the termination of fads is largely explained by the exhaustion of innovative possibilities. The drug has been tested in all of the apparently relevant settings; children have run out of new ways to twirl the Hula-Hoop.

Third, the faddish preoccupation means holding in abeyance many routine activities as well as awareness of drawbacks to the fads. So long as the fad is in full force, a sharp ingroup-outgroup sense insulates faddists against these concerns. But once the faddists run out of new variations they begin to be aware of the extent of their neglect of other activities and to consider possible dangers in the fad.

Hysterical contagion. Occasionally waves of fear find expression in a rash of false perceptions and symptoms of physical illness. Girls in an English school fainted in great numbers; women in Mattoon, Ill., reported being anesthetized and assaulted by a mysterious prowler. The best documented case is that of a clothing factory that had

Spread of physical symptoms through fear

to be closed down and fumigated because of reports of toxic insect bites—reports that could not subsequently be substantiated. The U.S. sociologist Alan C. Kerckhoff and the U.S. psychologist Kurt W. Back found that the crisis came after a period during which the women employees had performed unusual amounts of overtime work. The women who became ill from the mysterious insect bites had generally worked more overtime than others and had serious family responsibilities that they could not fulfill because of job demands. Afraid to refuse overtime work lest their job prospects be damaged, yet increasingly upset over neglect of family responsibilities, they found themselves in a conflict from which they could not extricate themselves. Illness from an insect bite provided an excuse to leave work for a day or two. The epidemic continued for about 11 days. It began immediately after a large shipment of foreign cloth had arrived, rendering plausible the assumption that some strange new insect had been introduced to the plant. The first women "bitten" were social isolates, lacking normal social defenses and controls. A rapid spread then took place among women who belonged to intimate cliques, in accord with the theory that social diffusion occurs most readily along well-established lines of social interaction. In the final stage the illness spread to others, irrespective of friendship ties or isolation.

Deviant epidemics. Obsessive behaviour also is observed within deviant groups in society. After Edward G. Robinson starred in the motion picture *Little Caesar* (1932), a rash of undersized juvenile delinquents aped his manner. In 1959 and 1960 there was a rash of incidents in which synagogues were desecrated, usually by painting Nazi swastikas on them, and anti-Semitic slogans were painted in public places. In the United States the epidemic began the day after Christmas and continued for nine weeks, encompassing 600 reported incidents. Incidents reached a peak in the third week, with the cycle in small communities lagging a little behind the large cities. In the early and late weeks Jewish synagogues, houses, and other specifically Jewish properties were the main targets. During the middle three weeks anti-Semitic symbols were often placed elsewhere, leading investigators to infer that during the peak of the epidemic many participants were drawn in who were less preoccupied with anti-Semitism than were those who initiated the incidents. Only a minority of the perpetrators were identified and arrested, but these were principally adolescent boys who worked together in small unorganized and heterogeneous groups. Some were strongly anti-Semitic in their attitudes, while others were no more hostile toward Jews than they were toward many other groups or aspects of society.

In this kind of episode socially disapproved feelings are given vent following an initial incident. Beginning with persons who have been holding back a specific feeling for some time, the epidemic builds up until persons with other types of suppressed feelings join in. As the epidemic recedes, these secondary participants drop out first.

Fashion. Fashion is much like fads and other collective obsessions, except that it is institutionalized and regularized, becoming continuous rather than sporadic, and partially predictable. Whereas fads often emerge from the lower echelons of society, and thus constitute a potential challenge to the class structure of society, fashion generally flows from the higher levels to the lower levels, providing a continuous verification of class differences. Continuous change is essential if the higher classes are to maintain their distinctiveness after copies of their clothing styles appear at lower levels. Fashions tend to change cyclically within limits set by the stabler culture.

Fashion as a show of class differences

Crazes. Another term frequently used to characterize collective obsessions is craze. The term is not analytically separate from "fad" and "fashion," but it does carry somewhat different connotations. Frequently it refers to a collective focus on important figures in the entertainment or sports world—Rudolph Valentino, Frank Sinatra, James Dean, the Beatles, Michael Jackson, and Pelé to name a few. Fans idolize these personalities, relish and mimic real or imaginary details of their lives, and often form clubs or societies to share their fascination. In many instances crazes suffer the same fate as fads—they die abruptly. In some cases, however, figures such as Sinatra and the Beatles outlast the craze and endure as public figures.

Personality idolization

The term craze also has a special connotation in the financial world. There crazes develop when the value of land, stock, or other merchandise is driven well above its intrinsic value by speculation, creating a boom. Such crazes are mainly modern phenomenon, since they require that there be surplus wealth and a flexible and storable medium of exchange. They represent the escalation of a buoyant confidence in the economic future that goes far beyond realistic limits. Financial crazes normally occur after a period of economic expansion and are associated with what seems to be the sudden emergence of a new area of opportunity. The postwar opening up of Spanish New World colonies to British trade was the occasion for the famous 18th-century South Sea Bubble. Combined with craze optimism is the fear of lost opportunity—that is, that the supply of land (or whatever) is not inexhaustible and that only those who buy early will benefit from the initial low prices. The famous crazes have generally received the stamp of authenticity from respected figures who themselves invested and endorsed the enterprise. No less a person than the king of England lost money when the South Sea Bubble burst. Speculative crazes in modern times evolve particularly out of stock exchange activities, although government controls have somewhat curtailed their volatility.

CROWDS

A thin line separates crowd activities from collective obsessions. The crowd is, first, more concentrated in time and space. Thus a race riot, a lynching, or an orgy is limited to a few days or hours and occurs chiefly within an area ranging from a city square or a stadium to a section of a metropolitan area. Second, a concern of the majority of the crowd (many participants do not always share the concern) is a collaborative goal rather than parallel individual goals. The "june bug obsession" cited earlier, in which dozens of women went home from work because of imaginary insect bites, could have turned into a crowd action if the women had banded together to demand a change in working conditions or to conduct a ceremony to exorcise the evil. Third, because the goal is collaborative, there is more division of labour and cooperative activity in a crowd than in collective obsessions. Finally, a major concern of a crowd is with some improvement or social change expected as a result of its activity. Labour rioters expect management to be more compliant after the riot; participants in a massive religious revival expect life in the community to be somehow better as a result.

The crucial step in developing crowd behaviour is the formation of a common mood directed toward a recognized object of attention. In a typical riot situation a routine police arrest or a fistfight between individuals from opposing groups focuses attention. Milling and rumour then establish a mood of indignation and hostility toward an identified enemy or enemies. In a collective religious experience there is usually an amazing event that rivets attention. Through elementary collective behaviour the mood is defined as religious awe and gratitude toward the supernatural and its agents.

As the mood and object become established, either an "active" crowd or an "expressive" crowd is formed. The active crowd is usually aggressive, such as a violent mob, though occasionally it acts to propel members into heroic accomplishments. The expressive crowd has also been called the dancing crowd because its manifestations are dancing, singing, and other forms of emotional expression.

Active crowds. The active crowd identifies an object or group of objects outside itself and proceeds to act directly upon it or them. It will brook no delay or interference, no discussion of the desirability of acting, and no dissent from its course of action. Because of the high pitch of crowd interaction, subtle and indirect courses of action cannot win crowd support, though members are highly suggestible to all proposals and examples for action in keeping with the mood and the object. The stage of transformation from shared mood to shared action constitutes the beginning of the true crowd or mob.

The crucial feature of this stage is overcoming the barriers to such behaviour as the destruction of property or violence toward persons—actions against which most people have strongly ingrained inhibitions. At least four aspects of the way crowd members feel about the situation make this possible. First, there is a sense of an exceptional situation in which a special moral code applies. The crowd merely carries further the justification for a special code of ethics incorporated in the slogan "You have to fight fire with fire!" Second, there is a sense of power in the crowd, with its apparent determination and uniform will, that overcomes the individual's doubts concerning his own ability to carry out a momentous task successfully. Third, there is a sense of impunity, of safety from personal injury and punishment so long as the individual is on the side of the crowd. And finally, there is a sense of inevitability—that the crowd aim will be accomplished regardless of the doubts and opposition of individuals.

Collapse of conventional restraints

Once the crowd breaks through the barrier of conventional restraints there is typically a "Roman holiday" period during which all restraint appears to be dropped. To the outsider, people seem to have gone mad. Rage is entirely uninhibited. But at the same time an atmosphere of intense enjoyment and release is evident. There is laughing and cheering as the violence and destruction become part of a tremendous carnival.

Under cover of the Roman holiday, people pursue many different interests. Looting for personal gain is infrequent in the early stages of rioting. The leading agents in bringing the mob into being are too preoccupied with their indignation for this. But once the general attack is under way, looting for gain, vandalism for fun, and attacks on specific objects to pay off old grudges become prevalent. In Russian and Polish pogroms of the 19th and early 20th centuries, peasants came with their carts to loot Jewish property after they heard that the pogrom was under way. Lynchings in the southern United States in the early part of the 20th century were frequently followed by general forays on black neighbourhoods.

The active crowd normally ends with a tapering-off period, which is sometimes preceded by a stage of siege. In riots of limited scale in which no massive police or military forces are used, the peak day is followed by a few more days of successively smaller numbers of widely scattered encounters. Often the last incidents are in areas not previously hit by rioting. There seems to be some internal mechanism limiting the duration of crowd behaviour, though whether it is fatigue, catharsis, or reassertion of ingrained standards of behaviour is uncertain. In serious riots, however, the police and other armed forces are brought into action long before the riot declines on its own. When police power is applied with only enough force to ensure a standoff between rioters and authorities, there is a period—usually ranging from one to three or four days—of siege. The mood of buoyancy gives way to a mood of dogged persistence. Rioters are more cautious and deliberate in what they do. The desire to have the riot over grows among the participants and in the community, but there is reluctance to give up the fight until concessions have been won.

Development of active crowds

A crowd develops only when a necessary sequence of events occurs and when conditions conducive to crowd development are present. There are at least six such conditions of importance. The first is a deep frustration that is shared by an important segment of the population and that has been festering for a considerable period of time. The frustration is especially poignant when widening intergroup contacts make the frustrated segment more vitally aware of its disadvantages, when its members have been encouraged by education or a public policy statement to aspire to relatively unattainable objectives, and when a period of steadily improving conditions is suddenly interrupted. Second is the presence of deep intergroup cleavages in society. A crowd must have not only a grievance but also an oppressor whom it can blame for its condition. Third is some contradiction in the value system of society, so that there is support both for the social arrangements that the group finds frustrating and for its demands for change. Fourth is a failure of communication, so that grievances can no longer be presented to the appropriate authorities with confidence that they will be given some consideration. Fifth is some failure in the system of control. Mobs often catch police unprepared. In many instances the police, by virtue of their class or ethnic identity, are in sympathy with mobs and unwilling to enforce order. Sixth are experiences leading people to hope that conditions will be improved as a result of violent or disruptive action. Many riots have the support of a well-developed ideology, or they follow occasions when demonstrations and other less extreme tactics have won gains. Among the reasons that mob actions do not soon recur in a given location are that the forces of order are usually strengthened, the hope of great gain is dampened, and channels of communication are often improved after a mob action.

Expressive crowds. Not all crowds act. In some crowds the participants are largely preoccupied with themselves or with one another, and with participation in a common experience. Beginning as early as the 7th century in Europe, and continuing throughout the Middle Ages, there were reported epidemics in which groups of people were caught up in a frenzy of dancing that continued until they dropped. Later a collective frenzy of dancing, singing, and shouting became a regular feature of frontier revivals in 19th-century America. Crowds that exceeded conventional limits of revelry have been common in many historical eras. In San Francisco in 1945, license for public violation of sexual mores characterized the day of celebration at the end of the war with Japan.

Expressive crowds may be secular or religious. What distinguishes them is that the production of a shared subjective experience is the crowd's measure of its accomplishment, rather than any action upon objects outside the crowd. One interpretation is that the same determinants of social unrest and frustration may give rise to both the expressive crowd and the active crowd, but the expressive crowd fails to identify an object toward which to act; hence members must release accumulated tension through motions and gestures expressing emotion. According to this view an expressive crowd can fairly quickly metamorphose into an active crowd if an object becomes apparent to them. Another interpretation sees the expressive crowd as equally equipped with an object, but with an object that must be acted upon symbolically rather than directly. Thus, one crowd engages in a wild dance to exorcise evil spirits, whereas another seeks to destroy buildings associated with the "establishment" that it blames for many ills.

The expressive crowd may serve best those types of frustrations requiring revitalization of the individual and group rather than direct modification of external circumstances. Expressive crowds may be especially frequent in periods of frustration and boredom over the predictability and routinization of life, from lack of a sense of meaning and importance in the daily round of life, and from a sense of interpersonal isolation in spite of the physical closeness of others.

PANIC

The word panic is often applied to a strictly individual, maladaptive reaction of flight, immobility, or disorganization stemming from intense fear. For example, a student "panics" during an examination and is unable to call upon his knowledge in answering questions, or a disaster victim in a situation of mild danger panics and flees into much greater danger. Individual panic frequently occurs as a unique individual response without triggering a similar reaction in others.

Panic as collective behaviour, however, is shared behaviour. When an entire military unit breaks into disorderly flight, a group pattern of orderly behaviour is replaced by a group pattern of panic.

Characteristics of panic

There are a number of distinguishing features to collective panic, four of which are noted here. First, several persons in social contact with one another simultaneously exhibit intense fear and either flee (or demonstrate disorganization leading toward flight) or remain immobile. Second, each individual's fear and his evaluation of the danger are augmented by the signals he receives from others. Third,

flight is indicated as the only conceivable course of action by the signals each is receiving from others. Fourth, the usual rules according to which individuals adjust their behaviour so as not to work at cross-purposes are nullified. In the more dramatic instances of collective panic, people trample one another in vain efforts to reach safety.

Four types of causes for collective panic are generally recognized. First, collective panic usually occurs in the kind of situation that arouses fear in any individual. Hence the psychological causes for individual panic are also the fundamental causes for collective panic.

A second cause of panic is the special character of the situation in which people find themselves. Students of responses to disaster observe that collective panic occurs only when people perceive a danger that is both immediate and severe, when they know of only a very limited number of escape routes from the danger, and when they believe those routes are being closed off so that the time for escape is extremely limited. The requirement that all three conditions be present underlines the observation that intense fear in situations from which there is apparently no escape elicits no collective panic and little individual panic.

Psychologists have suggested that collective panic be viewed as part of a broad class of individualistic crowds. Individualistic crowds include such phenomena as the crush and breakdown of order that sometimes occur at a bargain sale, or the transformation of an orderly ticket-window queue into a shoving and pushing crowd. All the usual mechanisms of crowd behaviour are in operation, but, in contrast to the lynch mob or race riot, the situation encourages the intensified pursuit of individual rather than collective goals.

Behaviour of passengers during the *Titanic* disaster

The situational explanation is not complete by itself, however, as indicated by such occasions as the sinking of the ocean liner *Titanic* with great loss of life but without panic. The ship was visibly sinking, and it was known that there were too few lifeboats for all the passengers, and yet men were frequently reluctant to board the lifeboats until all women and children on board had first been rescued. Hence the third set of causes is the interstimulation of elementary crowd behaviour, the milling, rumour, and social unrest, through which the group forms a collective view of the situation and of the appropriate behaviour. It is difficult to find any logical explanation for the difference in behaviour between the passengers on the *Titanic* and passengers who have panicked in other maritime disasters, except that a norm of gentility and heroism came to dominate the collective definition through these elementary processes.

Since the most dramatic feature of panic behaviour is every individual's disregard for his fellows' lives, many students believe that the fourth set of causes lies in the quality of every individual's relations with his fellows. The U.S. sociologists Kurt Lang and Gladys E. Lang view panic as the end point in a process of demoralization in which behaviour becomes privatized and there is a general retreat from the pursuit of group goals.

PUBLICS AND MASSES

Crowd behaviour and such related forms as fads and panics are often contrasted with "publics," in which more of an attitude of deliberation prevails. The most important distinction between crowds and publics is that people in the public recognize that there is a division of opinion about an issue and are prepared to interact with a recognition and tolerance of difference. Blumer defines the public as "a group of people who (a) are confronted by an issue, (b) are divided in their ideas as to how to meet the issue, and (c) engage in discussion over the issue." Another important difference is that the product of interaction in the public is public opinion, rather than the collective action or experience of collective ecstasy that eventuates from active and expressive crowds.

Publics are common in societies where public officials and institutional leaders are thought to be responsive to indications of public opinion. When this condition does not prevail, collective behaviour does not usually crystallize beyond the elementary forms, stopping with the establishment of a rumour grapevine. When disillusionment over official response to public opinion reaches a high pitch, publics either do not form or turn quickly into crowds that take direct action.

Comparison of crowds, publics, and masses

The public and crowd should be distinguished from the "mass." Members of a mass exhibit similar behaviour, simultaneously, but with a minimum of interaction. Masses include a wide range of groups. They include, for instance, people simultaneously reading the newspaper advertisement for a department store sale and simultaneously converging on the store with similar objects in mind; but masses also involve people converging in a disaster or a gold rush or a mass migration. In the public and the crowd, social interaction plays a large part in accounting for common definitions of an issue and similar views about how to deal with a problem. But in a mass a great many people react similarly to a common stimulus just because they have common attitudes and motivations. Election behaviour is often closer to the mass than to the public, when taboos on discussing controversial topics lead each person to make up his mind privately on the basis of what he gleans from the mass media of communication.

SOCIAL MOVEMENTS

Collective behaviour in crowds, panics, and elementary forms (milling, etc.) are of brief duration or episodic and are guided largely by impulse. When short-lived impulses give way to long-term aims, and when sustained association takes the place of situational groupings of people, the result is a social movement.

Characteristics of social movements. A movement is not merely a perpetuated crowd, since a crowd does not possess organizational and motivational mechanisms capable of sustaining membership through periods of inaction and waiting. Furthermore, crowd mechanisms cannot be used to achieve communication and coordination of activity over a wide area, such as a nation or continent. A movement is a mixture of organization and spontaneity. There is usually one or more organizations that give identity, leadership, and coordination to the movement, but the boundaries of the movement are never coterminous with the organizations. For example, although organizations such as California's Sierra Club are influential in the movement to preserve the natural environment, anyone who works for the cause and interacts with other workers for this purpose is a member of the conservationist movement. The famous John Brown was not a member of any major abolitionist organization, but his martyrdom made him a leader and symbol for the movement, even though organizational leaders were reluctant to recognize him.

(R.H.T./N.J.S.)

Social movements and social change. All definitions of social movement reflect the notion that social movements are intrinsically related to social change. They do not encompass the activities of people as members of stable social groups with established, unquestioned structures, norms, and values. The behaviour of members of social movements does not reflect the assumption that the social order will continue essentially as it is. It reflects, instead, the faith that people collectively can bring about or prevent social change if they will dedicate themselves to the pursuit of a goal. Uncommitted observers may regard these goals as illusions, but to the members they are hopes that are quite capable of realization. Asked about his activities, the member of a social movement would not reply, "I do this because it has always been done" or "It's just the custom." He is aware that his behaviour is influenced by the goal of the movement: to bring about a change in the way things have "always" been done or sometimes to prevent such a change from coming about.

The individual in the social movement

The membership. The quixotic efforts of bold, imaginative individuals do not constitute social movements. A social movement is a collectivity or a collective enterprise. The individual member experiences a sense of membership in an alliance of people who share his dissatisfaction with the present state of affairs and his vision of a better order. Like a group, a social movement is a collectivity with a common goal and shared values.

The sense of membership suggests that the individual is

subject to some discipline. In addition to shared values, a social movement possesses norms. These norms prescribe behaviour that will symbolize the member's loyalty to the social movement, strengthen his commitment to it, and set him apart from nonmembers. The norms prohibit behaviour that may cause embarrassment to the movement or provide excuses for attacks by opponents. Commitment is strengthened by participation in group activities with other members and by engaging in actions, individual or collective, that publicly define the individual as a committed member.

A social movement also provides guidelines as to how members should think. Norms of this kind constitute something resembling a "party line"—a definition of the "correct" position for members to take with regard to specific issues. There is subtle pressure on the individual to espouse this position even in the absence of personal knowledge of the arguments for it. Not every member can be expected to study and think through the philosophy that justified the movement and its values. Ideology provides him with a ready-made, presumably authoritative set of arguments.

One of the defining characteristics of a social movement is that it is relatively long lasting; the activity of the membership is sustained over a period of weeks, months, or even years rather than flaring up for a few hours or a few days and then disappearing. A social movement is usually large, but, like duration, largeness is only relative. Some social movements, lasting many decades, may enlist hundreds of thousands of members. Some movements take place within the boundaries of a specific secondary group, such as a religious association or a local community, and may include only a few score or a few hundred members.

The lack of formal structure

The exact size of a social movement is impossible to determine exactly, for membership is not formally defined. Indeed, one of the salient characteristics of a social movement is the semiformal character of its structure. It lacks the fully developed, formal structure of a stable association, such as a club, a corporation, or a political party. The leaders do not possess authority in the sense of legitimatized power, and members are not formally inducted. The informal, noncontractual quality of membership and the absence of formal decision-making procedures place a premium on faith and loyalty on the part of members. While not all members display these traits, the ideal member gives his total, unselfish loyalty to the movement. Since no legal obligation is assumed on becoming a member, either to conform to the movement's norms or to remain a member, commitment to the movement and its values becomes one of the most important sources of control. The deeply committed member, accepting without question the decisions and orders conveyed by the leaders, sacrificing self, family, and friends if required to do so, is likely to be regarded by outsiders as a fanatic. Some students of social movements, particularly those whose analysis has a psychoanalytic orientation, have suggested that the fanaticism of dedicated members results from individual psychopathological states. An alternative explanation is that the social movement becomes a reference group that provides the member with a new and deviant view of social reality. His basic assumptions about the nature of the social order become so divergent from those of the "normal" members of society that his logic and conclusions are incomprehensible to them.

Types of social movements. There is no single, standard typology of social movements. As various scholars focus on different aspects of movements, different schemes of classification emerge. Hence any social movement may be described in terms of several dimensions.

Dimensions of social movements

Many attempts at categorization direct attention to the objective of the movement. The social institution in or through which social change is to be brought about provides one basis for categorizing social movements as political, religious, economic, educational, and the like. It may be argued that all movements tend to be either political or religious in character, depending upon whether their strategy aims at changing political structures or the moral values of individuals.

A commonly used but highly subjective distinction is that between "reform" and "revolutionary" movements. Such a distinction implies that a reform movement advocates a change that will preserve the existing values but will provide improved means of implementing them. The revolutionary movement, on the other hand, is regarded as advocating replacement of existing values. Almost invariably, however, the members of a so-called revolutionary movement insist that it is they who cherish the true values of the society and that it is the opponents who define the movement as revolutionary and subversive of basic, traditional values.

Some attempts to characterize movements involve the direction and the rate of change advocated. Adjectives such as radical, reactionary, moderate, liberal, and conservative are often used for such purposes. In this context the designations "revolutionary" and "reform" are often employed in a somewhat different sense than that described above, with the implication that a revolutionary movement advocates rapid, precipitous change while a reform movement works for slow, evolutionary change.

Killian advances still another typology based on the direction of the change advocated or opposed. A reactionary movement advocates the restoration of a previous state of social affairs, while a progressive movement argues for a new social arrangement. A conservative movement opposes the changes proposed by other movements, or those seeming to develop through cultural drift, and advocates preservation of existing values and norms.

Turner and Killian argue that it is useful at times to categorize social movements on the basis of their public definition, the character of the opposition evoked, and the means of action available to the movement. This scheme is designed to eliminate the subjective evaluation of goals inherent in such categories as reform and revolutionary. A movement that does not appear to threaten the values or interests of any significant segment of society is publicly defined as respectable. If there is no competing movement advocating the same objective, it is also nonfactional. The respectable nonfactional movement must contend primarily with the problems of disinterest and token support, but it has access to legitimate means of promoting its values. A respectable factional movement must contend with competing movements advocating the same general objective but also has access to legitimate means of extending its influence. A movement that appears to threaten the values of powerful and significant interest groups within the society is publicly defined as revolutionary and encounters violent suppression. As a result, it is denied access to legitimate means of promoting its program. Another type of movement is defined as neither respectable nor dangerous but as peculiar; this type, seen as odd but harmless, encounters ridicule and has limited access to legitimate means.

Social movements may also be categorized on the basis of the general character of their strategy and tactics; for instance, whether they are legitimate or underground. The popular distinction between radical and moderate movements reflects this sort of categorization. An obvious difference between types of movements depends upon their reliance on violent or nonviolent tactics. But a nonviolent movement may also be defined as revolutionary or radical because it accepts civil disobedience, rather than legal or parliamentary maneuvering, as a major feature of its strategy. It should be added that the distinction between violent and nonviolent movements is a relative one because a movement may shift rapidly from one to the other as it develops.

The dynamics of social movements. As an enduring, sustained collectivity a social movement undergoes significant changes during its existence. This characteristic has led some scholars to formulate a theory of a "life cycle" or "natural history" common to all social movements. Other scholars question the value of the life-cycle approach to social movements, arguing that empirical studies of numerous movements fail to support the notion of invariant stages of development. Smelser suggests as an alternative a value-added theory, which postulates that while a number of determinants are necessary for the occurrence of a social movement, they need not occur in any particular

The pattern of social movements

order. Some may be present for some time without effect only to be activated later by the addition of another determinant. At most it can be said that the idea of the life cycle permits the discovery of conditions that must be present if any movement is to proceed from one stage to another. It may also help identify the conditions that cause a movement to change direction. Still, it can be said that a social movement has a career; for as it endures it always undergoes changes in many of its characteristics, though the sequence of these changes may vary from movement to movement.

Progressive changes in leadership and membership. One of the most apparent changes is a shift in leadership. In its earliest stages the strongest influence on a movement is likely to be the charismatic leader who personally symbolizes its values. At some point intellectuals play a leadership role by contributing to the developing ideology of the movement. And if a movement endures and grows for any length of time, administrative leaders arise who are concerned with the practical matters of organization and strategy. Influence in the movement may shift between these types.

Usually the membership of a movement grows during its career, which introduces an element of greater heterogeneity. In the early stages the followers typically are deeply committed with an almost fanatical dedication to the movement's values. If the movement gains a measure of respectability in some segment of society, members may be acquired who are not deeply committed. They are likely to have significant reservations about the movement, and their participation is sporadic. This heterogeneity also can be the basis for internal conflict in a movement. On the other hand, if a movement is publicly defined as revolutionary and subjected to harsh oppression, the membership is likely to be reduced mainly to deeply committed converts or to fanatics who derive some satisfaction from the feeling of being persecuted.

Progressive changes in goals and strategies. The goals rarely remain unchanged. As the movement endures and grows, they are likely to become broader and vaguer than they were at the beginning. Proposals for limited, specific reforms become embedded within programs of general social reform. As the leaders and members begin to acquire a sense of power through early victories, the power orientations of the movement may increase. Acquisition of greater power by the population segment that the movement purportedly represents, rather than the implementation of the values of the movement, then becomes a goal. At the same time, the statement of the movement's aim in acquiring power becomes vaguer and more utopian.

Diminishment of original purpose

Changes also occur in the strategy, which may tend in either of two general directions. It may emphasize personal transformation, bringing about social change by converting a majority of society to implement the values by their actions. Or it may emphasize a strategy of societal manipulation, changing social institutions so that the program may be implemented without regard to the number of people favouring the new order. Failure of a movement to gain a large number of converts, combined with indications that it has at its disposal effective means of coercion, leads to a shift to this type of strategy.

Strategy and changes in strategy are strongly influenced by the relationship of the social movement to the larger society and to other social movements. The social structure and the prevailing belief system may suggest either that change can be brought about by changing the hearts and minds of the individual members or that individuals have little effect on the social order. A public definition of the movement as dangerous and subversive may force it to rely increasingly on a strategy of societal manipulation, including violent tactics. The opposition posed by a countermovement may have the same effect, making attempts at persuasion difficult and dangerous and causing a nonviolent, noncoercive movement to use force.

Relations between structural elements. As a collectivity, a social movement is characterized by an emergent social structure and a culture. The social structure is reflected in the relationship between leaders and followers, the culture in the values and norms.

Unlike an association, a social movement does not possess legitimate leaders in the sense of being endowed with authority through some formal process. Leaders must constantly substantiate their claims to leadership by demonstrating the effectiveness of their influence on the followers. There is a relationship of reciprocal influence. The followers, for their part, lack institutionalized means of making their influence felt, such as referendums, legislatures, or periodic elections of leaders. It falls to the leaders, therefore, to formulate policies and decisions that will strike a responsive note in their following. Having advanced such proposals, they must rely on either persuasion or coercion to create the illusion that these are collective decisions made by the entire movement. Propaganda thus becomes an important tool of leadership.

Interior structures

Propaganda is also important for maintaining morale and unity. A social movement lacks both the intimacy of a primary group and the formal boundaries of an association. The speeches and writings of leaders serve, in part, to assure the followers of the size, the strength, and the potential for success of the movement—matters difficult for the followers to observe directly. Movements do utilize interpersonal relations to enhance their unity, encouraging small groups of members to meet frequently in circumstances in which they can form personal ties. Mass meetings and parades, with the accompanying ritual, reduce the feelings of isolation that scattered members may experience. Of extraordinary value to a movement is the example of martyrs whose fate arouses indignation in the members, symbolizes unreserved commitment, and lightens the burden of sacrifices.

The culture of a movement encompasses norms and values. Norms are standardized expectations of behaviour developed by members. Values include the program and the ideology. The program is the scheme of change, the new social order that the movement proposes to bring about. The ideology is a body of ideas justifying the program and the strategy of the movement. It usually includes a reinterpretation of history, a projection of the utopia that the success of the movement will introduce, a projection of the disastrous consequences of failure, and a reevaluation of the relationship between population segments and the movement.

The causes of social movements. Both individual psychological states and the characteristics of a society at a particular time may be considered as causes of social movements.

Psychological factors. Individual factors are psychological states that either convince a person to join a movement or so weaken his commitment to conventional groups that he is willing to risk their disapproval because of his belief in an unpopular cause. Failure to achieve a satisfying status and identity within normal membership groups may be such a factor. The prestige and sense of belonging, which such a person may gain as a member of a social movement, may be even more important to him than the values of the movement. Alienation, feelings of powerlessness, hopelessness, and estrangement from society may predispose an individual to participation. Some scholars argue, however, that there are different kinds of alienation. One type leads merely to apathy and resignation. Political alienation, however, reflects a loss of faith in the political community and predisposes the individual to join a movement that challenges it.

Deprivation, discontent, and frustration are frequently assumed to be sufficient causes for initiating or joining a social movement. The relationship is not a simple one, however. There is little evidence that the most deprived segments of a population are the most likely to participate in social movements. The concept of relative deprivation has been used to explain the fact that persons who could be much worse off than they are but still feel deprived in comparison with even more fortunate groups often play a prominent part in social movements.

Social factors. An important task of the student of social movements is to identify those conditions under which social movements are most likely to arise. While the existence of widespread poverty and suffering might seem sufficient to give rise to efforts at reform, it must

be emphasized again that some basis for hope must also exist to stir people to make the effort. Paradoxically, partial alleviation of conditions of deprivation may provide such a basis, serving as the impetus for the formation of a social movement just as things seem to be getting better. The success of other people similarly situated, such as victorious revolutionaries in a neighbouring nation, may be another source of hope.

Social movements and discontent

More general theories of the origin of social movements, such as those of Smelser, Turner, and Killian, suggest that social change may result in strains or conflicts in one or more crucial aspects of the social order. Normative strain arises when changing conditions create a situation in which the established norms no longer lead to the attainment of important, accepted values. Strain in values arises when the values themselves seem to interfere with the satisfaction of important needs of a segment of the society. This sort of strain often arises when different groups, such as immigrants, minorities, or the younger generation, develop values that conflict with those of more established groups. Even with little change in norms and values, changes in social structure reflected in the failure of important functionaries to play their roles adequately may lead to discontent.

The general nature of the belief system existing in the culture of a society affects the likelihood that social movements will arise and defines the type that will occur. For example, a system that is essentially fatalistic is less conducive to social movements, particularly those with a strategy of societal manipulation, than one that emphasizes the perfectibility of man and his control over his own fate.

The consequences of social movements. It has been suggested that the committed participant in a social movement undergoes a psychological reorganization. It is clear that his new sense of security and importance is acquired at the sacrifice of autonomy. As a loyal member he tends to let the leaders do his thinking for him, suppressing doubts as to the validity of the ideology and the wisdom of the leader's decision. He repeats their arguments in a dogmatic fashion; persons who are not in the movement find it difficult to debate with him since they start from different premises. His perception is selective in a different way from theirs. The ideology, for example, may lead him to view all governmental authorities as villains, while the ordinary citizen views them as legitimate leaders, some good, some bad. The end product of this surrender of autonomy may be an altered worldview. Some things taken for granted before becoming part of the movement will never seem the same again, even after leaving the discipline of the movement.

The end products of social movements as collectivities attempting to change the social order cannot be analyzed simply in terms of success or failure. Failure may come as a result of ruthless suppression of the movement or through widespread apathy. A movement may wither away because too few take it seriously and it does not develop enough power to force its program on society. Sometimes the remnants may linger for a long time as a cult, oriented inward toward the gratifications that the members obtain from participation but making no serious effort to change the social order.

Consequences of success

Success is most apparent when a movement manages to have its power legitimized as authority. In a successful revolution the social movement becomes the new source of authority and respectability, and opposition to its values is defined as counterrevolutionary. In other instances, the movement achieves power through secession. Failing to compel acceptance of its values in the larger group or society, the members withdraw into a new social system in which they can attempt to implement the values separately from a hostile or indifferent society.

A less obvious form of success is the institutionalization of the values or some part of them. Accepting the legitimacy of the movement's values, the traditional associations in the society incorporate them into their own values and implement them without a transfer of authority to the movement. Thus the U.S. Socialist Party has seen many of its proposals adopted by the two major political parties and the government without winning a major election or overthrowing the government. Sometimes the social movement itself is institutionalized by being accorded authority as the legitimate custodian of the new values. The movement is then transformed into a bureaucratic association, as happened with the American labour movement of the early 20th century and the Congress Party of India after British rule ended. (L.M.K./Ed.)

Theories of collective behaviour

Because much collective behaviour is dramatic, unpredictable, and frightening, the early theories and many contemporary popular views are more evaluative than analytic. The French social psychologist Gustave Le Bon identified the crowd and revolutionary movements with the excesses of the French Revolution; the U.S. psychologist Boris Sidis was impressed with the resemblance of crowd behaviour to mental disorder. Many of these early theories depicted collective behaviour as an atavism, in which the evolutionary accomplishments of civilization were stripped away and human behaviour returned to an earlier stage of development. Freud retained this emphasis in viewing crowd behaviour and many other forms of collective behaviour as regressions to an earlier stage of childhood development; he explained, for example, the slavish identification that followers have for leaders on the basis of such regression.

Social and revolutionary theories

More sophisticated recent efforts to treat collective behaviour as a pathological manifestation employ social disorganization as an explanatory approach. From this point of view collective behaviour erupts as an unpleasant symptom of frustration and malaise stemming from cultural conflict, organizational failure, and other social malfunctions. The distinctive feature of this approach is a reluctance to take seriously the manifest content of collective behaviour. Neither the search for enjoyment in a recreational fad, the search for spiritual meaning in a religious sect, nor the demand for equal opportunity in an interest-group movement is accepted at face value.

An opposite evaluation of many forms of collective behaviour has become part of the analytic perspective in revolutionary approaches to society. From the revolutionist's point of view, much collective behaviour is a release of creative impulses from the repressive effects of established social orders. Revolutionary theorists such as Frantz Fanon depict traditional social arrangements as destructive of human spontaneity, and various forms of crowd and revolutionary movements as man's creative self-assertion bursting its social shackles.

INDIVIDUAL MOTIVATION THEORIES

Among the analytic theories that seek to eschew evaluation, the most popular ones stress individual motivation in accounting for collective behaviour. Frustration and lack of firm social anchorage are the two most widely used explanations for individual participation in collective behaviour of all kinds. In the psychiatric tradition, frustration heightens suggestibility, generates fantasy, brings about regressions and fixations, and intensifies drives toward wish fulfillment so that normal inhibitions are overcome. Since most forms of collective behaviour promote thoughts that are otherwise difficult to account for and that breech behavioral inhibitions, this is often a fruitful source of explanation.

Psychiatric and sociological traditions

In the sociological tradition of Émile Durkheim, absence of firm integration into social groups leaves the individual open to deviant ideas and susceptible to the vital sense of solidarity that comes from participation in spontaneous groupings. Drawing upon both the psychiatric and the sociological traditions, Erich Fromm attributed the appeal of mass movements and crowds to the gratifying escape they offer from the sense of personal isolation and powerlessness that people experience in the vast bureaucracies of modern life. Extending Karl Marx's theory of modern man's alienation from his work, many contemporary students attribute faddism, crowds, movements of the spirit, and interest-group and revolutionary movements to a wide-ranging alienation from family, community, and country, as well as from work.

According to the approach suggested by the U.S. political scientist Hadley Cantril, participation in vital collectivities supplies a sense of meaning through group affirmation and action and raises the member's estimate of his social status, both of which are important needs often frustrated in modern society. Eric Hoffer, a U.S. philosopher, attributed a leading role in collective behaviour to "true believers," who overcome their own personal doubts and conflicts by the creation of intolerant and unanimous groups about them.

INTERACTION THEORIES

Sociologists and social psychologists, without denying the place of individual motivation in any complete explanation for collective behaviour, have more often stressed a distinctive quality or intensity of social interaction. The U.S. sociologist Ernest Burgess, along with Park, associates collective behaviour with "circular reaction," a type of interaction in which each person reacts by repeating the action or mirroring the sentiment of another person, thereby intensifying the action or sentiment in the originator. Blumer adds a subtlety to this theory by sharply distinguishing circular reaction from "interpretative interaction," in which the individual first interprets another's action and then makes a response usually different from the stimulus action. Another stream of thought has stressed difference of intensity rather than kind of interaction. Following the lead of the French social scientist Gabriel Tarde and the French psychologist Alfred Binet, many investigators have looked for clues that normal imitative tendencies and suggestibility may be intensified in collective behaviour. An important approach is based on the U.S. psychologist Floyd H. Allport's criticism of Le Bon and William McDougall, a British-born U.S. psychologist, for their concept of "group mind," and for their apparent assumption that collective behaviour makes people do things to which they are not predisposed. Allport insisted instead that collective behaviour involves merely a group of people doing what they previously wanted to do but for which they lacked the occasion and the support of like-minded associates.

Contagion, convergence, and emergent norm

These interaction theories have been labeled contagion and convergence theories, respectively—the former stressing the contagious spread of mood and behaviour; the latter stressing the convergence of a large number of people with similar predispositions. Both have sought to explain why a group of people feel and act (1) unanimously, (2) intensely, and (3) differently from the manner in which they customarily act. Other interaction theorists have challenged the assumption of unanimity, proposing that in most kinds of collective behaviour a single mood and course of action is established with such force and intolerance that the many who privately dissent are silenced, creating an illusion of unanimity. Rather than contagion, it is an emergent norm or rule that governs external appearances and, to a lesser extent, internal convictions in collective behaviour.

Freud, too, stressed a distinctive pattern of interaction in collective behaviour. The key to these groupings is the desire to possess a beloved leader. Because the leader is unattainable, and because his attentions must be shared among many followers, a relation of identification is expressed in the demand for uniformity that the followers insistently impose on each other, according to the example of the leader.

SOCIAL CHANGE

A final set of theories stresses characteristics of social organization that generate collective behaviour. Collective behaviour is commonly seen by sociologists as a normal accompaniment and medium for social change, relatively absent in periods of social stability. With the more or less continuous shifts of values in any society, emerging values are first given group expression in collective behaviour; efforts to revitalize declining values also bring forth collective behaviour. Again, the constant readjustments in the power of different population segments are implemented and resisted through collective behaviour. Because it is a means of communication, and because it is always characterized by novel or intensified control over individuals, collective behaviour also arises to bypass blockages in communication and to install an emergent order when formal or informal regulation of behaviour is inadequate.

The most comprehensive theory specifying necessary conditions for the development of most major forms of collective behaviour was advanced by Smelser. He noted six conditions that must be present: (1) the social structure must be peculiarly conducive to the collective behaviour in question; (2) a group of people must experience strain; (3) a distinctive type of belief must be present to interpret the situation; (4) there must be a precipitating event; (5) the group of people must be mobilized for action on the basis of the belief; and (6) there must be an appropriate interaction between the mobilized group and agencies of social control. The detail for each condition varies with the type of collective behaviour.

Since the early 1970s two new strands of theory and empirical research have arisen, one in the United States and one in western Europe. The first, called resource mobilization theory, takes as its starting point a critique of those theories that explain social movements as arising from conditions of social disorganization and strain and as finding their recruits among the isolated and alienated in society. By contrast, research mobilization theorists argue that the success of social movements rests mainly on the resources that are available to it; this means forming coalitions with already-existing organizations, securing financial support, and mounting effective and organized campaigns of political pressure. As a result of this emphasis, resource mobilization theorists downplay the factor of ideology—and irrational factors generally—in the study of social movements.

The second theory is the new social movement theory. It derives from an intellectual dissatisfaction with the predominantly Marxist view that treats social movements as reflecting a fundamental struggle among classes organized around economic production. That theory, it is argued, has become less relevant as these classes have been drawn into collective bargaining, the welfare system, and other social advancements within the state. The "new social movements" that have arisen in their place are interpreted as struggles against the social inequalities, the dominance of the mass media, and other features of postindustrial capitalism and the welfare state. These include youth, feminist, peace, and ecological movements, as well as the rise of group conflicts based on ethnicity and race. Jürgen Habermas, a German sociologist, interpreted such movements as protests against the excessive size and rationality of the state and its bureaucracies and their intrusion into the private worlds of individuals.

The results of collective behaviour

THE VARIETY OF EFFECTS

Short-term effects. The most notable immediate effect of all kinds of collective behaviour is to alter the salience of various problems, issues, and groups in public awareness. Popular concern about disarmament grew large as "Ban-the-Bomb" demonstrations proliferated during the late 1950s and early 1960s; then public interest waned as demonstrations became infrequent or ceased. A fad calls attention to recreational needs; the circumstances surrounding a panic monopolize public attention. Second, all forms of collective behaviour contribute to polarizations, forcing people to take sides on issues and eliminating the middle ground. Often a three-sided conflict develops among the two polarized groups and mediators who wish to de-emphasize divisive issues altogether. Third, every instance of collective behaviour either alters or strengthens the makeup of group and community leadership. The swings of fashion discredit some clothes designers and boost others to prominence. A riot or a wildcat strike usually reveals the inability of established leaders to control their members and produces emergent leaders from among the spokesmen acceptable to members.

Contingencies. How the immediate effects of collective behaviour are translated into long-term consequences depends upon several contingencies, of which four merit

attention. First, the nature of the response by authorities affects the immediate course of the collective behaviour. Some evidence suggests that alarmed and repressive reactions strengthen polarization, that moderate reactions strengthen the mediation viewpoint, and that inaction or ineffectual action facilitates efforts toward usurpation of authority.

Second, the response of authorities affects public definitions of the meaning of the collective behaviour. Publics have variously defined particular fads as harmless diversions, threats to authority and order, threats to health and well-being, visitations of the Holy Spirit, and possession by the devil, treating them quite differently in consequence. Lynchings are vigilante actions, or they are criminal subversions of justice. Riots can be viewed as mass criminality or as social protest. Social movements are defined as respectable, or as peculiar but harmless, or as dangerous and revolutionary, evoking polite support, embarrassed avoidance, or active repression, respectively.

A third contingency affecting the aftermath of collective behaviour concerns the nature and strategy of the countermovements or counterfads that arise. When the countermovement arises, acquires a bitter and reactionary tone, and becomes a backlash, polarization and heightened disorder often lead to demands for order at any cost, at the expense of any amelioration that might otherwise have occurred. But backlash is often self-discrediting as "extremism," and over the long run it sometimes pushes many people onto the side of amelioration. Countermovements that avoid the backlash pattern typically try to undermine the group they oppose by taking some of the latter's aims as their own, thereby helping to effect reforms sought in the initial protest.

Conventionalization of collective behaviour

Finally, the effect of collective behaviour depends upon the ubiquitous process of conventionalization. In a spontaneous fad or mob action, participants usually copy the pattern of earlier incidents with which they are familiar, so that separate incidents in a wave of collective behaviour exhibit a similarity indicating the development of customary ways of rioting, or playing at a fad, and possibly even of panicking. When incidents are repeated, a gradual accommodation between participants in collective behaviour and the authorities becomes routinized. Once the behaviour is conventionalized in this fashion, there are increasing efforts to create and use the conventionalized form of collective behaviour for private and public aims. Much advertising seeks to create fads in conventionalized ways. Political rallies, sports rallies, and some of the ceremonies of established religious organizations seek to conventionalize the enthusiasm and sense of solidarity of expressive crowds. Social movements rapidly acquire stable organizations, sects become denominations, political movements become political parties or are absorbed into parties, and humanitarian movements become stabilized as associations to promote some form of human betterment. Conventionalization extends the influence of orienting ideas, but it also ensures compromise and abandonment of the most disruptive and controversial features of the initial behaviour.

Long-term effects. In the long run it is difficult to be sure whether a particular type of collective behaviour actually makes a difference or whether it is merely a shadow cast by passing events. Scattered collective behaviour is endemic in every society. But when there is widespread discontent, collective behaviour soon becomes a prominent feature of group life. When there are no exciting new ideas—such as the liberal humanitarian vision of the 18th and 19th centuries, the Socialist idea of the 19th and 20th centuries, and the nationalist mystique of the 20th century—collective behaviour consists principally of expressive behaviour, panics, and unfocused disruption or intergroup vengeance such as pogroms. This kind of collective behaviour probably contributes little to change. But when there is a new perspective to give meaning to discontent, many forms of collective behaviour appear to become agents of change. Even a recreational fad becomes a form of self-assertion for a rising class or age group. Le Bon suggested that in a period of widespread discontent crowd action serves to destroy an old order in preparation for a new one. Social movements help to build the new order.

One view holds that collective behaviour supplies a testing ground on which new ideas are tried out for general acceptability and on which groups test their strength against forces of resistance. The outcome of this testing is sometimes change and sometimes public demonstration that the old order is still viable. This view suggests that collective behaviour has as great a function to play in maintaining social stability as in implementing social change.

ATTEMPTS AT CONTROL

Attempts to control collective behaviour vary according to whether change or stability is sought. Advocates of change seek to control countermovements and backlash crowds, as well as those expressive crowds and fads that anesthetize people to their grievances, whereas advocates of stability seek to control crowds and movements that undermine public order or threaten revolution. Advocates of both change and stability likewise make use of collective behaviour in achieving their aims. The volatile and unpredictable nature of all collective behaviour renders manipulation and control highly problematic, however, and masters of control, such as the French revolutionary Robespierre, have often been victims of the followers they once manipulated.

The most sensitive and difficult control problem occurs at the moment of the first precipitating incident and during the stage of transformation in an active crowd. A show of weakness—or maybe even unnecessary repression—will escalate the crowd into the Roman-holiday stage. It is essential to identify spokesmen who command a hearing with the crowd—often not the established group leaders—and open serious negotiations with them. Poorly arranged negotiating sessions before television cameras are easily turned into occasions for incitement of the crowd. If the provocations of excessive policing are avoided and one or two dramatic concessions of great symbolic importance made, a cooling-off period may be secured in which more comprehensive measures to relieve tensions in the situation can be undertaken.

Once collective behaviour is fully escalated there is seldom any control technique available except massive suppression, and some experts believe that crowd behaviour will spring up again if crushed before it has substantially run its course. Interference with an expressive crowd, and even with many fads and instances of hysterical contagion, often turns it into a hostile, active one. As the intensity of feeling begins to decline, the time is then ripe to quicken the end of crowd behaviour by intensifying negotiations with spokesmen respected by the crowd. (R.H.T./N.J.S.)

BIBLIOGRAPHY

Theoretical and general studies: Theories of collective behaviour are introduced in HADLEY CANTRIL, *The Psychology of Social Movements* (1941, reprinted 1973); SIGMUND FREUD, *Group Psychology and the Analysis of the Ego* (1922, reissued 1975; originally published in German, 1921); WILLIAM A. GAMSON, *Power and Discontent* (1968); ERIC HOFFER, *The True Believer: Thoughts on the Nature of Mass Movements* (1951, reissued 1980); RICHARD T. LAPIERE, *Collective Behavior* (1938); and DAVID L. MILLER, *Introduction to Collective Behavior* (1985). See also JOHN C. BRIGHAM, *Social Psychology* (1986). The major general treatments of the subject include HERBERT BLUMER, "Collective Behavior," in ALFRED M. LEE (ed.), *Principles of Sociology*, 3rd ed. (1969), a classic sociological statement of a widely used approach; ROGER BROWN, "Mass Phenomena," in GARDNER LINDZEY (ed.), *Handbook of Social Psychology*, vol. 2, pp. 833–876 (1954); and STANLEY MILGRAM and HANS TOCH, "Collective Behavior: Crowds and Social Movements," in GARDNER LINDZEY and ELLIOT ARONSON (eds.), *Handbook of Social Psychology*, 2nd ed., vol. 4, pp. 507–610 (1968), comprehensive reviews presented by psychologists; ROBERT R. EVANS (ed.), *Readings in Collective Behavior*, 2nd ed. (1975), a collection of classic journal articles; KURT LANG and GLADYS ENGEL LANG, *Collective Dynamics* (1961), a standard textbook; NEIL J. SMELSER, *Theory of Collective Behavior* (1963, reissued 1971), a classic theoretical treatise and text; RALPH H. TURNER, "Collective Behavior," in ROBERT E.L. FARIS (ed.), *Handbook of Modern Sociology*, pp. 382–425 (1964), an analytic statement of the field for the advanced student in sociology; RALPH H. TURNER and LEWIS M. KILLIAN, *Collective Behavior*, 3rd ed.

(1987), a standard textbook; and JOHN LOFLAND, *Protest: Studies of Collective Behavior and Social Movements* (1985).

Specialized studies: Elementary collective behaviour is studied in GORDON W. ALLPORT and LEO POSTMAN, *The Psychology of Rumor* (1947, reprinted 1975); TAMOTSU SHIBUTANI, *Improvised News: A Sociological Study of Rumor* (1966); and FREDRICK KOENIG, *Rumor in the Marketplace: The Social Psychology of Commercial Hearsay* (1985). Responses to disaster are the subject of GEORGE W. BAKER and DWIGHT W. CHAPMAN (eds.), *Man and Society in Disaster* (1962); WALTER LORD, *A Night to Remember* (1955, reissued 1984); HARRY E. MOORE, *Tornadoes over Texas: A Study of Waco and San Angelo in Disaster* (1958); and UNITED STATES. FEDERAL EMERGENCY MANAGEMENT AGENCY, *Behavior and Attitudes Under Crisis Conditions: Selected Issues and Findings* (1984). For discussion of collective obsessions, see DAVID CAPLOVITZ and CANDACE ROGERS, *Swastika 1960: The Epidemic of Anti-Semitic Vandalism in America* (1961); JOHN CARSWELL, *The South Sea Bubble* (1960); ALAN C. KERCKHOFF and KURT W. BACK, *The June Bug: A Study of Hysterical Contagion* (1968); and CHARLES MACKAY, *Memoirs of Extraordinary Popular Delusions,* 3 vol. (1841, reissued in 1 vol. as *Extraordinary Popular Delusions and the Madness of Crowds,* 1981).

Crowds: E. LOUIS BACKMAN, *Religious Dances in the Christian Church and in Popular Medicine* (1952, reprinted 1977; originally published in Swedish, 1945); HUGH DAVIS GRAHAM and TED ROBERT GURR (eds.), *Violence in America: Historical and Comparative Perspectives* (1969; published also as *The History of Violence in America*); GUSTAVE LE BON, *The Crowd: A Study of the Popular Mind,* 2nd ed. (1968, reprinted 1984; originally published in French, 1895); *Report of the National Advisory Commission on Civil Disorders* (1968); ARTHUR F. RAPER, *The Tragedy of Lynching* (1933, reprinted 1970); GEORGE RUDÉ, *The Crowd in History: A Study of Popular Disturbances in France and England, 1730–1848,* rev. ed. (1981); CARL F. GRAUMANN and SERGE MOSCOVICI (eds.), *Changing Conceptions of Crowd Mind and Behavior* (1986); and FRANK STAGG, E. GLENN HINSON, and WAYNE E. OATES, *Glossolalia: Tongue Speaking in Biblical, Historical and Psychological Perspective* (1967).

(R.H.T.)

Social movements: RUDOLF HEBERLE, *Social Movements: An Introduction to Political Sociology* (1951), develops general theories but focuses on the relationship between social movements and political parties. CLARENCE W. KING, *Social Movements in the United States* (1956), develops general principles from the analysis of selected social movements. HANS TOCH, *The Social Psychology of Social Movements* (1965); and MUZAFER SHERIF and CAROLYN W. SHERIF, *Social Psychology* (1969), represent theoretical approaches, placing greater emphasis on individual motivational and perceptual processes. LYFORD P. EDWARDS, *The Natural History of Revolution* (1927, reprinted 1970); CRANE BRINTON, *The Anatomy of Revolution,* rev. ed. (1965); and GEORGE S. PETTEE, *The Process of Revolution* (1938, reissued 1971), represent attempts to develop general theories of revolution as a type of social movement through the analyses of American and European revolutions. A similar effort based on studies of revolutions in Latin America and the Middle East is found in CARL LEIDEN and KARL M. SCHMITT, *The Politics of Violence* (1968, reprinted 1980). There are numerous studies of particular social movements. Representative of those that include theoretical propositions, as well as historical descriptions, are E.J. HOBSBAWM, *Primitive Rebels: Studies in Archaic Forms of Social Movement in the 19th and 20th Centuries,* 3rd ed. (1971); CORA DU BOIS, *The 1870 Ghost Dance* (1939, reprinted 1976); KENELM BURRIDGE, *Mambu: A Melanesian Millennium* (1960, reissued as *Mambu: A Study of Melanesian Cargo Movements and Their Ideological Background,* 1970), studies of nativistic movements; and FREDERICK KRANTZ (ed.), *History from Below: Studies in Popular Protest and Popular Ideology in Honour of George Rudé* (1985). Analyses of Communism and Nazism are found in PHILIP SELZNICK, *The Organizational Weapon: A Study of Bolshevik Strategy and Tactics* (1952, reissued 1979); and THEODORE ABEL, *Why Hitler Came into Power* (1938, reprinted 1986). Essays on the Algerian revolution are found in FRANTZ FANON, *Studies in a Dying Colonialism* (1965; originally published in French, 1959). Analyses of social movements in the United States are found in THOMAS H. GREER, *American Social Reform Movements: Their Pattern Since 1865* (1949, reprinted 1980); LEWIS M. KILLIAN, *The Impossible Revolution? Black Power and the American Dream,* 2nd ed. (1975); JEROME H. SKOLNICK, *The Politics of Protest* (1969); and ALEC BARBROOK and CHRISTINE BOLT, *Power and Protest in American Life* (1980). A source on the new social movements is JÜRGEN HABERMAS, *Die Neue Unübersichtlichkeit: Kleine politische Schriften V* (1985).

(L.M.K./N.J.S.)

Cologne

One of the key inland ports of Europe, Cologne (German: Köln) is the fourth largest city in Germany and the largest city in the *Land* ("state") of Nordrhein-Westfalen (North Rhine-Westphalia). It is the historic, cultural, and economic capital of the Rhineland. Cologne's commercial importance grew out of its position at the point where the huge traffic artery of the Rhine (German: Rhein) River intersected one of the major land routes for trade between western and eastern Europe. In the Middle Ages it also became an ecclesiastical centre of significance and an important centre of art and learning. This rich and varied heritage is still much in evidence in present-day Cologne. Cologne is the seat of a university and the see of a Roman Catholic archbishop. Its cathedral, the largest Gothic church in northern Europe, was designated a World Heritage site in 1996; it is the city's major landmark and unofficial symbol.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Cologne is situated about 21 miles (34 kilometres) northwest of Bonn and 25 miles southeast of Düsseldorf. It lies 210 feet (65 metres) above sea level, just below where the Rhine enters the fertile North German Plain. The river at this point is navigable to seagoing vessels. The immediate surroundings of Cologne are varied. The picturesque hills of the Bergisches Land lie to the east, while on the west is another group of hills forming a chain called the Ville. The North German Plain stretches away to the north and northwest, and the Rhine Valley winds to the southeast toward Bonn.

The area of the modern city is about 156 square miles (405 square kilometres), the greatest distance from west to east being about 17 miles and from north to south about the same. There are 85 districts, divided into nine city areas (*Bezirke*). Most of the city lies on the left (west) bank of the river, but it also incorporates a cluster of suburbs on the right bank, some of which were annexed in 1975. Average temperatures in the Cologne area are 36° F (2° C) in January and 64° F (18° C) in July.

The city layout. The semicircular shape of the Inner City was originally determined by a defensive wall, four miles long, that was completed in about 1200. The wall enclosed several formerly separate parishes and afforded protection for some 35,000 to 40,000 people. (At that time Cologne was bigger than Paris.) The flat side of the semicircle was formed by the Rhine. In the 1880s the medieval fortifications were demolished and replaced by a chain of ring roads, called the Ringstrassen.

Although Cologne has spread far beyond the confines of the Ringstrassen, its focal point is still within this area, the Inner City (Innenstadt). There are found the main shopping and business streets—such as the Hohe Strasse (north–south) and Schildergasse (west–east), both of which have been closed to motor vehicles—as well as the city's historic buildings. Several bridges span the river at Cologne; five of them were rebuilt after World War II, and the rest were postwar additions.

A large proportion of Cologne's area consists of parkland, woods, lakes, sports facilities, and open areas. Two major park systems follow roughly the concentric patterns of old fortifications around the Innenstadt. The first is just outside the Ringstrassen and includes (from north to south) zoological and botanical gardens, the Stadtgarten, and the Volksgarten. The second, the Outer Greenbelt, is a wooded area that stretches for miles around the western and southern edge of the city and contains extensive recreation grounds and the Müngersdorfer Stadion. On the right bank of the river are the Rheinpark, a large green area; the KölnMesse, a convention centre; and the KölnArena, a covered multi-use arena for sporting events and musical concerts.

Cologne cathedral

Architecture. Cologne cathedral (Kölner Dom) eclipses in its size and grandeur all other historic buildings in the city. Its twin towers rise 515 feet above the city centre. After an earlier cathedral on the site was destroyed by fire in 1248, it was decided that a new one would be built in the Gothic style, emulating the cathedrals of France. The choir was completed in 1320 and consecrated in 1322. Construction continued until 1560, when it came to a halt. The cathedral stood unfinished until 1842, when work was resumed. In 1880 the enterprise was finally completed. The building was badly damaged by air raids in 1944; but by 1948 the choir had been restored and was again in regular use, as was the rest of the interior by 1956.

The 14th-century stained-glass windows in the choir are considered especially beautiful. On the high altar is a massive gold shrine containing what are said to be relics of the Magi, sent to Cologne from Milan in 1164. This shrine, begun by Nicholas of Verdun in 1182 and completed in about 1220, is considered one of the finest examples of medieval goldwork. The altar in the Lady Chapel (on the south wall of the choir) has a triptych, "The Adoration of the Magi," painted between about 1440 and 1445 by Stefan Lochner, the outstanding painter of the Cologne school.

By the south side of the cathedral lies a reminder of Cologne's still more ancient past: the mosaic floor of a banquet hall in a great Roman villa. The floor is now incorporated in the Römisch-Germanisches Museum. Other Roman remains in Cologne include a well-preserved 1st-century-AD tower from the earliest city wall, the remains of the North Gate, a large portion of the Praetorium (governor's residence) visible in the basement of the restored Gothic Rathaus ("Town Hall"), and a mausoleum in Weiden on the outskirts. The Ubier-Monument, discovered in the 1960s, dates from the period of the Ubii occupation of the area (see below *History*). Remains of the medieval walls can still be seen, and three of the original 12 gates survive: the Eigelsteintor, Hahnentor, and Severinstor. The Bayenturm, a medieval tower, stands near the Rhine.

Medieval churches

Apart from the cathedral, the Inner City possesses many other noble churches, largely built in the prosperous Middle Ages. Particularly in evidence is the Romanesque style, of which the best examples are Sankt Gereon, Sankt Severin, Sankt Ursula, Sankt Maria im Kapitol, Sankt Kunibert, Sankt Pantaleon, Sankt Aposteln, and Gross Sankt Martin. After sustaining severe wartime damage, these churches underwent a program of restoration, the completion of which was celebrated in 1985. The 14th-century

A passenger boat on the Rhine River passes the Cologne cathedral (Kölner Dom).

Antoniterkirche, a secularized monastery church, was made over to the Protestants in 1802 and became the first public Lutheran church in Cologne.

Secular medieval buildings

Among Cologne's secular medieval buildings that suffered in World War II and have undergone reconstruction are the Overstolzenhaus, a 13th-century Romanesque house, and the Rathaus, with its 16th-century porch. The Gürzenich, or Festhaus ("Banquet Hall"), of the merchants of the city (1441–47), reconstructed as a concert and festival hall, and the 16th-century Zeughaus ("Arsenal"), which contains a historical museum, were both restored to their medieval form only on the outside.

These ancient buildings share the crowded city centre with modern offices, shops, a theatre and opera house (opened in 1957), and, just north of the cathedral, the railway station. Near the perimeter of the city is the new town hall. Located about a mile from the cathedral is the 798-foot Fernmeldeturm ("Telecommunications Tower"; 1981).

THE PEOPLE

Cologne is the fourth in population of Germany's cities, after Berlin, Hamburg, and Munich. About 85 percent of its population is of German nationality; of the remainder, most are southern European guest workers who have moved to the city since the 1970s, chiefly from Turkey and Italy but also from the Balkan states. The predominant religion of the German community is Roman Catholicism, but there is also a large Protestant minority. There is also a sizable Muslim community and a small Jewish one.

THE ECONOMY

Finance and industry. The city remains a banking centre, as it was in the Middle Ages, and it is the site of one of the world's oldest commodity and stock exchanges. A centre of the automotive industry, it is the headquarters of the Ford Motor Company's European operations. Insurance has assumed a major position, as have engineering, machinery, chemicals, and pharmaceuticals. Other manufactures include chocolate and the city's famous eau de cologne. The city is also a major media centre, with many publishing houses and production centres for radio and television. In addition, several important economic organizations, such as the Federation of German Industries (Bundesverband der Deutschen Industrie), have their headquarters in Cologne, and numerous major trade fairs are held there annually.

Transportation. Cologne is the busiest rail junction in the country and a major node for Germany's and Europe's evolving high-speed passenger rail network. Autobahns radiate outward from the peripheral road that encircles the city. The Cologne/Bonn-Konrad Adenauer Airport, located midway between the two cities, offers international passenger service and is an important centre for air cargo.

The Rhine harbour, important since Roman days, has become one of the larger inland ports in Germany. Small oceangoing craft use the river, and there are several ship lines for sightseeing on the Rhine. Intracity transport consists of streetcars, buses, and a subway system.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Cologne is the administrative centre of one of the five major administrative districts of Nordrhein-Westfalen. The city is governed by an elected council, which is presided over by an *Oberbürgermeister* ("chief mayor"). Many governmental services, such as welfare, planning, transportation, and cultural affairs, however, are controlled by the state government.

State services

Education. The University of Cologne, founded in 1388, was dissolved in 1798 (during the period when the French occupied the city) and refounded in 1919. Teacher-training colleges, a school of sports, and colleges for the study of music, engineering, administration, and other professions and trades are also located in the city.

CULTURAL LIFE

Cologne is rich in museums and galleries. These include the Wallraf-Richartz and Ludwig museum complex, with an exceptionally comprehensive collection ranging from paintings of the medieval Cologne school to contemporary art; the Schnütgen Museum of medieval ecclesiastical art; the Museum of Oriental Art, with artworks from China and Japan; and the Rautenstrauch-Joest Museum, with ethnological collections. The Roman and Germanic Museum houses artifacts from the period of the migrations of the Germanic peoples and that of the Roman occupation. Special exhibitions are held in the Josef-Haubrich Hall of Art exhibition centre near the Neumarkt.

Throughout most of the year, Cologne provides a variety of musical programs. Particularly notable are the Gürzenich concerts and those held in the concert hall of the Westdeutscher Rundfunk (WDR; "West German Radio"), the high reputation of the latter being largely due to the WDR's encouragement of contemporary music. A full repertoire is offered in theatre and opera as well, and the municipal theatre has its own ballet ensemble.

Carnival celebrations

The annual Rhenisch pre-Lenten carnival is celebrated with great ceremony, culminating in the Rosenmontag ("Rose Monday") festival before Ash Wednesday. Notable citizens have included the Dominican scholar Albertus Magnus, the novelist Heinrich Böll, and the statesman Konrad Adenauer.

History

EARLY SETTLEMENT AND MEDIEVAL GROWTH

After Julius Caesar destroyed the Eburones in 53 BC, the Roman general Agrippa colonized the area with another tribe called the Ubii, who came from the right bank of the Rhine. A fortified settlement was established on the site in about 38 BC. This was the birthplace of Agrippina the Younger, who was the wife of the emperor Claudius, and it was at her request that the title of Roman colony was conferred upon the town in AD 50. It was named Colonia Claudia Ara Agrippinensium, shortened to Colonia; later it was made the headquarters of the governor of Lower Germany. After AD 258 it was for a time the capital of a splinter empire ruled by Postumus and comprising Gaul, Britain, and Spain. In 310 the emperor Constantine the Great built a castle and a permanent bridge to it across the Rhine. Ceramics and glass were manufactured in Cologne in Roman times. About 456 it was conquered by the Franks, and it soon became the residence of the kings of the Ripuarian part of the Frankish kingdom.

A Christian community existed in Cologne probably as early as the 2nd century, and the town is first mentioned as a bishopric in 313. Charlemagne made it an archbishopric in the late 8th century; by the 10th century the archbishop dominated the city, receiving a wide range of tolls, customs duties, and other payments. The city's industry and trade grew during the Middle Ages, especially from about the 10th century, and increasingly bitter conflicts developed between the wealthy merchants and the archbishop. The former sought commercial and political freedom, the latter the preservation of his temporal power, which was augmented from the 13th century when the archbish-

Prosperity in the Middle Ages

op became one of the electors privileged to choose the German king. It was not until the Battle of Worringen, in 1288, that the archbishop was finally defeated and the city of Cologne secured full self-government. From that time, Cologne was, in fact, a free imperial city, although it was only officially recognized as such in 1475.

Until the end of the 14th century, the government of the city was in the hands of the wealthy patricians; but, in 1396, after a bloodless revolution, a new municipal constitution was established under which the 22 branches of the guilds became the basis of the government, for they elected a council that had power over all internal and external affairs.

This medieval period was a splendid one for Cologne. It was a prominent member of the mercantile Hanseatic League, and its merchants had probably the most extensive connections and the most varied trade of all the German towns. Crafts included textile manufacturing, bookmaking, leatherworking, enameling, and metalworking, the work of Cologne's goldsmiths being particularly fine. The arts and religion flourished there also. Three of the greatest Roman Catholic scholars and theologians of the medieval Scholastic movement—Albertus Magnus, Thomas Aquinas, and John Duns Scotus—all taught in Cologne's schools. After the Thirty Years' War (1618–48), however, the city declined. As late as 1794, when the French occupied Cologne, public Protestant services were still banned, and the city has remained predominantly Roman Catholic. The Jewish community, which had existed from the time of Constantine the Great, was expelled in 1424, and until 1794 no Jew was allowed to remain overnight in the city.

THE 19TH AND 20TH CENTURIES

Cologne's history as a free imperial city ended when it was taken by France in 1794; and, when the archbishop elector died in 1801, the see was left vacant and not restored until 1821. In 1815 Cologne passed to Prussia, and from that time a new era of prosperity began. A wide range of industries flourished, and a chamber of commerce was established, the oldest in Germany. When the railways were built, its geographical position made it an ideal railway centre. The population grew from 41,685 in 1801 to 372,529 in 1900. Liberal points of view were represented in the 19th century by the *Rheinische Zeitung,* edited (1842–43) by Karl Marx and Moses Hess, while the Socialist *Neue Rheinische Zeitung* was edited (1848–49) by Marx, Friedrich Engels, and Ferdinand Freiligrath.

The city's growth was interrupted by World War I. Under Konrad Adenauer—the future chancellor of West Germany who was *Oberbürgermeister* of Cologne from 1917 until he was deposed by the Nazis in 1933—growth resumed, especially in suburban areas and in the laying out of new industrial parks. By 1939 the population had reached 768,352. In World War II, Cologne sustained 262 air raids. There were 20,000 casualties, and the city was left in ruins, with nearly all the dwellings in the old town damaged and 91 out of 150 churches destroyed. In March 1945, the war's end for Cologne, the population had sunk to 40,000. By December, however, there were 447,000 in the city, and the population continued to rise rapidly while the work of clearance and reconstruction was undertaken. Since the war the process of growth has continued, with the development of new industrial areas and satellite towns and the improvement of transportation, and Cologne has regained its place as the economic and cultural centre of northwestern Germany.

Colombia

The Republic of Colombia (República de Colombia) occupies the northwestern corner of the South American continent. Its 1,000 miles (1,600 kilometres) of coast to the north are bathed by the waters of the Caribbean Sea, and its 800 miles of coast to the west are washed by the Pacific Ocean. The country is bordered by Panama, which divides the two bodies of water, on the northwest; Venezuela and Brazil on the east; and Peru and Ecuador on the south. Its area of 440,831 square miles (1,141,748 square kilometres) includes the San Andrés y Providencia archipelago, located off the Nicaraguan coast in the Caribbean, some 400 miles northwest of the Colombian mainland. The population is largely concentrated in the mountainous interior, where Bogotá, the national capital, is situated on a high plateau in the Andes Mountains.

The only American nation that is named for this discoverer of the New World, Colombia presents a remarkable study in contrasts, both in its geography and its society. The lofty snow-tipped peaks of the country's interior cordilleras tower high above equatorial forests and savannas where surviving Indian groups still follow the lifeways and traditions of their ancestors. In the cooler mountains, at intermediate elevations, modern cities are juxtaposed with traditional rural landscapes where mestizo farmers cultivate their small plots of coffee, corn (maize), and other crops. The more accessible Atlantic Lowlands, dominated by large livestock haciendas and a tri-ethnic population, have a distinctively different character.

Colombia strongly reflects its history as a colony of Spain. It is often referred to as the most Roman Catholic of the South American countries, and most of its people are proud of the relative purity of their Spanish language. Its population is heavily mestizo (of mixed European and Indian descent) but with substantial negroid admixture on the coasts. The Colombian economy is heavily dependent on the production of coffee, a crop that is highly sensitive to fluctuations in the world market. Agriculture still occupies a substantial part of the population, but employment in urban manufacturing and service industries has become increasingly important. About one-third of the inhabitants live in the six largest metropolitan areas. Political instability is closely tied to the unequal distribution of wealth, which, again, has strong historic antecedents. Illicit trade in drugs, a complex and growing issue, has become a major disruptive factor in the economy. The population has grown rapidly, and Colombia now ranks with Argentina as one of the two most populous nations in Spanish-speaking South America.

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Few countries boast such striking physical variety as does Colombia. Its broken, rugged topography, together with its location near the Equator, creates an extraordinary diversity of climates, vegetation, soils, and crops. The Andean cordillera, one of the world's great mountain ranges, dominates the landscape of the western part of the country, where most of the people live. North of the border with Ecuador the cordillera flares out into three distinct parallel ranges. Two great river valleys, those of the Magdalena and the Cauca, separate them and provide avenues of penetration from the Atlantic coastal lowlands into the heart of the country. Volcanic activity in the geologic past blocked the middle course of the Cauca River to form a great lake that once filled the western inter-Andean trough for some 120 miles south of Cartago. The river eventually broke through the dam to leave the level floor of the Cauca Valley at some 3,000 feet (980 metres) above sea level; today it is one of the nation's most productive agricultural areas.

The Colombian cordilleras belong to the northern portion of the great Andean mountain system, which extends along the Pacific coast of South America. The Andes are among the world's most youthful mountain ranges and among the highest. The geology and history of this northern sector is less well understood than that of the central and southern parts. It is clear, however, that the entire cordillera has evolved through the subduction of the crumpled margin of the Nazca Plate and, to the north, the Caribbean Plate, under the more rigid but lighter South American Plate, represented by the ancient Guiana and Brazilian shields. These tectonic forces, similar to those found elsewhere around the Pacific rim, continue to operate, as is evidenced by the high frequency of often destructive earthquakes. At the Pasto Massif, near the Ecuador border, the mountains divide into the Cordillera Occidental (Western Range), which runs parallel to the Pacific coast, and the Cordillera Central (Central Range), which, with its numerous volcanoes, forms the backbone of the system and runs in a generally southwest to northeast direction. At the Great Colombian Massif of the Cordillera Central, near the San Agustín Archeological Park, the Cordillera Oriental (Eastern Range) branches off in a more decidedly northeasterly direction.

Of the three ranges, the nonvolcanic Cordillera Occidental, which forms the barrier between the Cauca Valley and the rain-drenched Pacific coast, is the lowest and least populated. Two passes of less than 5,000 feet between Cali and Buenaventura on the Pacific coast mark the lowest depressions in the range. Elsewhere the crest is much higher, exceeding 12,000 feet at Mount Paramillo in the department of Antioquia. From there the Cordillera Occidental fingers north into the three distinct *serranías* of Abibe, San Jerónimo, and Ayapel, forested ranges that drop gradually toward the piedmont plains of the Caribbean littoral. A lesser topographic feature on the Pacific coast, the Baudó Mountains, separated from the Cordillera Occidental by the valley of the Atrato River, which empties into the Caribbean Gulf of Urabá, represents a southward extension of the Isthmus of Panama.

The Cordillera Central

The Cordillera Central is the highest of the Andean ranges of Colombia, rising to an average height of 10,000 feet. It is a continuation of the Ecuadorian volcanic structure. Crystalline rocks are exposed at several places on its flanks and are the foci of localized gold and silver deposits. Sandstones and shales of the Tertiary Period

(from 65,000,000 to 2,500,000 years ago) are also a part of the older basement that has been capped by ash and lava derived from some 20 volcanoes of the Quaternary Period (within the past 2,500,000 years). Several of the latter reach well into the zone of permanent snow, above 15,000 feet. The highest are Mount Huila (18,865 feet), southeast of Cali, and the Ruiz-Tolima complex (17,716 feet) between Manizales and Ibagué. The fertile ash from their eruptions has produced the high, cool plateaus of Nariño department and the often steep slopes to the north that support much of Colombia's coffee production. In November 1985 Mount Ruíz erupted, melting the snow and ice that covered it and sending great mudflows downslope, destroying the city of Armero and killing more than 25,000, in one of the country's greatest catastrophes.

North of Mount Ruíz, near Sonsón in the department of Antioquia, the volcanic Cordillera Central gives way to the deeply weathered, granitic Antioquia batholith (an exposed granitic intrusion), a tableland averaging some 8,000 feet above sea level. It is divided into two parts by the deep transverse cleft of the Porce River, which occupies the U-shaped valley in which is situated the expanding metropolis of Medellín, Colombia's second city. The batholith contains gold-bearing quartz veins, which were the source of the placer gravels that gave rise to an active colonial mining economy. Beyond Antioquia the lower, remote San Lucas Mountains extend northward toward the confluence of the Magdalena and Cauca rivers.

The Cordillera Oriental

The massive Cordillera Oriental, separating the Magdalena Valley from the eastern plains (the Llanos), is composed chiefly of folded and faulted marine sediments and older schists and gneisses. Narrow to the south, it broadens out in the high, unsettled massif of Sumapaz, with elevations up to 13,000 feet. High plateaus were formed in the Quaternary Period by the deposition of sediments in depressions that had been occupied by lakes. The most important of these is the savanna area called the Sabana de Bogotá, site of the national capital. Farther northeast beyond the deep canyons cut by the Chicamocha River and its tributaries, the Cordillera Oriental culminates in the towering Sierra Nevada del Cocuy (18,028 feet). Beyond this point, near Pamplona, the cordillera splits into two much narrower ranges, one extending into Venezuela, the other, the Perijá Mountains, forming the northern boundary range between Colombia and Venezuela. The Perijás then descend northward toward the Caribbean to the arid Guajira Peninsula, the northernmost extension of the Colombian mainland.

The isolated Sierra Nevada de Santa Marta, an imposing fault-bounded granitic massif rising 18,947 feet (5,775 metres), the highest mountain in the country, ascends abruptly from the Caribbean littoral to snow- and ice-covered summits. The Atlantic Lowlands spread out southward behind it. Although it is a distinct geomorphic unit and not a part of the Andes, some geologists have suggested that it might be considered an extension of the Cordillera Central, from which it is separated by the Mompós depression in the lower Magdalena Valley.

The coastal plains

The steep and rugged Andean mountain masses and the high intermontane basins descend into plains that extend along the Caribbean and Pacific coasts and across the eastern interior toward the Orinoco and Amazon river systems. From the shores of the Caribbean Sea inland to the lower spurs of the three major cordilleras extends a slightly undulating savanna surface of varying width, generally known as the Atlantic Lowlands (also called the Caribbean Coastal Lowlands). Dotted with hills, and with extensive tracts of seasonally flooded land along the lower Magdalena and the Sinú rivers, it surrounds the inland portion of the Sierra Nevada de Santa Marta. A much narrower lowland apron extends along the Pacific shoreline from the point of Cape Corrientes southward to the Ecuadorian border.

A wide range of features characterize the country's two coastlines. Steep and articulated bays, inlets, capes, and promontories accentuate the shoreline on the Pacific side toward the Panama border and on the Caribbean side where the sea beats against the base of the Sierra Nevada de Santa Marta. These features are interspersed with sandy beaches, along with barrier islands and brackish lagoons.

The eastern lowland

The eastern two-thirds of the country lying beyond the Andes differs from cordilleran Colombia in practically all aspects of physical and human geography. The eastern lowland extends from the Venezuela boundary along the Arauca and Meta rivers in the north to the Peruvian–Ecuadorian border stream, the Putumayo, some 600 miles to the south, and from the base of the Cordillera Oriental eastward to the Orinoco–Negro river line, a distance of more than 400 miles. A region of great topographical uniformity, it is divided into two contrasting natural landscapes by a major vegetation boundary. In southern Colombia the Amazonian rain forest, or *selva*, reaches its northern limit. From the Guaviare River northward the plains between the Andes and the Orinoco River are mostly grass covered, forming the largest savanna complex in tropical America. This part of the lowland is called the Llanos Orientales or simply the Llanos.

In the central part of the plain, between the Guaviare and Caquetá rivers, the eroded rocks of the ancient Guiana shield are exposed, producing a broken topography of low, isolated mountains, tablelands, and buttes with rapids in the streams. This slightly higher ground forms the watershed between the Amazon and Orinoco systems. Some 60 miles south of Villavicencio the elongated, forested La Macarena Mountains rise 8,000 feet from the surrounding lowlands, an isolated tropical ecosystem.

Drainage and soils. In Colombia's rugged terrain the rivers have been historically important as routes of transportation and settlement. By far the most important river system is the Magdalena. Its drainage basin, including that of its major tributary, the Cauca, covers some 100,000 square miles, or about 22 percent of the surface of the country. Within it are found most of the nation's socioeconomic activity and more than three-fourths of its population. Originating in the Andean Páramo de Las Papas, the Magdalena flows northward in the structural depression between the Cordilleras Central and Oriental for almost 1,000 miles to empty into the Caribbean near Barranquilla. The Dique Canal, begun during the colonial period, links its lower course with the coastal city of Cartagena. The Cauca River, which contributes a substantial part of its total flow, rises in the mountains south of Popayán and, after passing through the floor of the Cauca Valley near Cali, occupies deep canyons in most of its passage through the departments of Caldas and Antioquia before emerging onto the floodplain of the lower Magdalena.

The Magdalena River system

The Magdalena, a shallow, braiding stream in its upper and middle course, served as a major transport artery for most of the country's history, but deforestation and soil erosion has led to silting and increased flow variation so that its role has become less significant. Because of its rapids, the Cauca has never been of much importance for the moving of goods. Among the major affluents of the Magdalena, besides the Cauca, are the Sogamoso, César, San Jorge, Saldaña, Lebrija, and Carare rivers. The Sinú and the Atrato are other major streams that flow directly into the Caribbean.

The great eastern watershed is subdivided into two sections, the waters flowing into the Orinoco and the Amazon rivers, which carry them to the Atlantic Ocean. The Arauca and Meta, the lower reaches of which cross into Venezuela, and the Vichada, Inírida, and Guaviare are among the main rivers that flow into the Orinoco. Among the streams that flow into the Amazon are the Vaupés, Caquetá, and Putumayo. The rivers that flow into the Pacific are relatively short, descending rapidly from the Cordillera Occidental to the sea. They carry large volumes of water, however, because they drain areas of extremely heavy rainfall. Among the rivers belonging to the Pacific watershed are the Baudó, San Juan, Dagua, Naya, San Juan de Micay, Patía, and Mira, which rises in Ecuador.

The wide variety of soils encountered in the country reflects climatic, topographic, and geologic conditions. Those best suited for modern, mechanized agriculture are the alluvial soils found in the principal river valleys, such as the Magdalena, Cauca, Sinú, César, and Ariguaní. The former lake beds of some of the inter-Andean basins, such as the Sabana de Bogotá and the Ubaté and Chiquinquirá

valleys, also fall into this category. Elsewhere, soils of volcanic origin, especially in the coffee-growing districts of the Cordillera Central, can be exceptionally productive if protected from erosion. The Quindío department, west of Bogotá, is especially renowned for its rich soils.

Climate. Because of the country's close proximity to the Equator, its climate is generally tropical and isothermal (without any real change of seasons). Temperatures vary little throughout the year. The only genuinely variable climatic element is the amount of annual precipitation. Climatic differences are related to altitude and the displacement of the Intertropical Convergence Zone between the two major air masses from which the Northeast Trade Winds and the Southeast Trade Winds originate. Human settlement is more oriented to vertical zoning in Colombia than anywhere else in Latin America.

The climate of the tropical rain forest in the Amazon region, the northern Pacific coast, and the central Magdalena Valley is marked by an annual rainfall of more than 100 inches (2,500 millimetres) and annual average temperatures above 74° F (23° C). A tropical monsoon climate, marked by one or more dry months but still supporting rain forest vegetation, occurs along the southern Pacific coast, on the Caribbean coast, and at places in the interior in the Quindío department and near Villavicencio.

The tropical savanna conditions of alternately wet and dry seasons comprise the predominant climate of the Atlantic Lowlands; the dry season occurs from November to April, and the wet season (broken by dry periods) from May to October. This climate is found also in the Llanos region and in part of the upper Magdalena Valley. It is characterized by an annual rainfall of 40 to 70 inches and annual average temperatures usually above 74° F (23° C). The dry season, accompanied by dust and wind, coincides with the true winter of the Northern Hemisphere.

A drier savanna climate prevails on the Caribbean littoral from the Gulf of Morrosquillo to La Guajira Peninsula in the northeast. The rains normally occur in two brief periods (in April and in October to November, respectively) but rarely exceed 30 inches annually. The average temperature is hot—more than 81° F (27° C)—with the daily range greatest where the humidity is low. This type of climate also occurs in the rain shadows of the deep gorges of such rivers as the Patía, Cauca, Chicamocha, and Zulia and in parts of the upper Magdalena Valley. The climate reaches near-desert conditions in the far northern department of La Guajira.

In the mountain regions temperature is directly related to altitude. Average temperatures decrease uniformly about 3° F per 1,000 feet of ascent (0.6° C per 100 metres). Popular terminology recognizes distinct temperature zones (*pisos térmicos*), which are sometimes referred to as *tierra caliente* (up to about 3,000 feet); *tierra templada* or *tierra del café* (3,000 to 6,500 feet); and *tierra fría* (6,500 to 10,000 feet). The majority of Colombians live in the interior cordilleras in the *tierra templada* and the *tierra fría* zones. The *tierra templada* has moderate rainfall and temperatures between 65° F (18° C) and 75° F (24° C). In the *tierra fría,* Bogotá, at 8,660 feet above sea level, has an average of 223 days of precipitation, although the average rainfall is scarcely 40 inches. Its average temperature is 57° F (14° C). The climate of the high mountain regions—the *páramos,* ranging from 10,000 feet to about 15,000 feet—is characterized by average temperatures below 50° F (10° C), fog, overcast skies, frequent winds, and light rain or drizzle. At altitudes above 15,000 feet there is perpetual snow and ice.

The *páramos*

Plant and animal life. The diversity of life forms and life zones in Colombia has impressed observers since the days of the German explorer Alexander von Humboldt. The complex pattern of climate, soil, and topography has produced an extraordinary range of plants and plant communities that vary through both vertical and horizontal zones. They range from the mangrove swamps of the coasts, the desert scrub of La Guajira, the savanna grasslands and gallery ecosystems of the Atlantic Lowlands and the eastern Llanos, and the rain forest of Amazonia and the Chocó region to the widely diverse and complex montane ecosystems of the Andean slopes.

Human intervention has vastly altered what must have been the original vegetation of the Atlantic Lowlands and the Andean region. Forests probably originally covered all but the highest and driest areas, where the soils were unsuited to support them. Today, in the inner Andes, they are restricted to the steepest, most inaccessible slopes and to areas of especially high rainfall. Elsewhere pasture, crops, or degraded scrub and grass have replaced the original cover of broadleaf evergreen trees. The first chroniclers often described the Andes as sparsely wooded, a condition they usually attributed to Indian agriculture and burning. In more recent times, with the increasing number of European cattle, the area in grassland has been vastly extended, both in the mountains and on the Atlantic Lowlands. Introduced grass species of African origin are particularly conspicuous.

Even in the most lush forest tracts that remain, such as those that flank the outer sides of the eastern and western ranges, there is much evidence of earlier human occupation. These wet montane forests are characterized by lianas, mosses, orchids, and bromeliads and by such economically valued plants as cinchona; the latex-bearing balata; ivory nut, or tagua; and the giant American bamboo. Lumbering has had a minor role because of the singular difficulty of access as well as the absence of forests of any one commercial species. In modern times technological advances have made possible the exploitation of forest species in accessible parts of the Atrato River basin and on the Pacific coast near Buenaventura.

The distinctive *páramo* biome of the equatorial high mountains reaches its greatest development in Colombia. This alpine-type vegetation is characterized by tussock grasses, cushion plants, and the treelike *frailejón* (*Espeletia*), a curious looking hairy-leafed genus of some 50 different species. Fire-resistant and adapted to low temperatures and high humidity, it gives special character to the *páramo* landscape. The lower *páramo,* below 12,000 feet, is a transitional belt in which scattered clumps of trees occur. Despite its bleak and forbidding climate, much of the *páramo* has been significantly altered by human activity, especially wood cutting and burning to promote better grazing. Agriculture has also impinged on its lower reaches, but extensive tracts remain relatively untouched by humans.

The *páramo* biome

The animal life of the forests of the Amazon and Pacific coastal Chocó regions is particularly rich and has supported a considerable export trade to North American and European zoos. It includes anteaters, sloths, several monkey species, tapirs, peccaries, the spectacled bear, deer, and such large tropical rodents as the agouti, paca, and capybara. Carnivores include pumas and jaguars, which were considered endangered species by the 1980s, and raccoons.

Amazonian fauna

Bird habitats are also influenced by altitude, and many species are specific to narrow altitudinal bands, ranging upward and downward only very short distances. The extremely lush birdlife encompasses more than 1,500 species, including toucans, hummingbirds, and those that migrate from North America. Among the reptiles, turtles, lizards, snakes, caimans, and crocodiles abound. Some quite unusual species inhabit the land, including earthworms that grow up to six feet in length. Freshwater fish include catfish, *bocachica,* and characin (small, brightly coloured tropical fish). Electric eels also inhabit the inland waters. The Magdalena and Cauca once supported rich river fisheries, but pollution and unrestrained commercial exploitation have taken a heavy toll.

Settlement patterns. Colombia can be divided into five traditional geographic regions: the Atlantic Lowlands, the Pacific coastal region, the Andean region, the eastern Llanos, and the Amazonian rain forest.

Of early colonial importance, the Atlantic Lowlands is now second to the Andean region in population and economic importance. It contains some 15 percent of the population, much of it concentrated in Barranquilla, Cartagena, and Santa Marta, the country's principal Caribbean ports. Cattle raising and mixed agriculture are the traditional economic activities, but large-scale commercial farming, especially of rice, cotton, and bananas, has been successful. Irrigation has expanded since the mid-20th

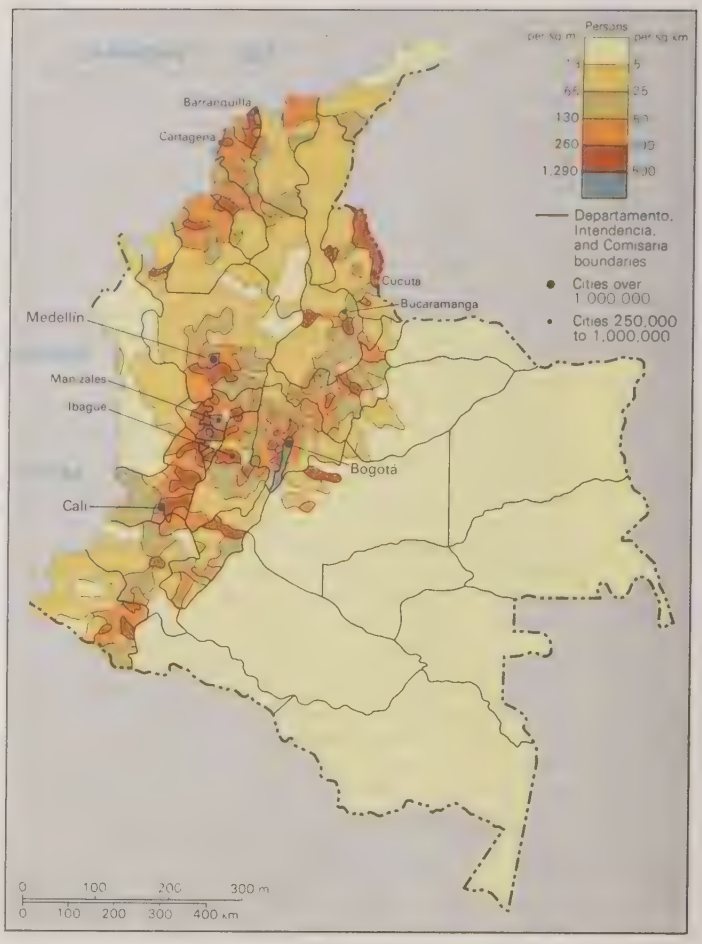
century, especially in the valleys of the Sinú and César rivers. Bananas are grown for export in the Urabá region.

The Pacific coast, including the department of Chocó, with its lush rain forest and infertile soils, is sparsely inhabited. Most of its people are descendants of liberated African slaves who settled in agricultural clearings along the rivers. It has little commercial activity, and the only port of note and the main population centre is Buenaventura.

The Andean region is the centre of the national political and economic power, with most of the country's population and large cities, including Bogotá, Medellín, and Cali, the three most populous. The Cauca Valley, with its vast tract of alluvial soil, the Sabana de Bogotá, and the Antioquia highlands are perhaps the most dynamic centres of economic activity and growth.

Andean settlement

Although the Llanos and the Amazonian rain forest together make up nearly two-thirds of the country, they contain only about 2 percent of the population. About half of this percentage is in the department of Meta in the Llanos, where cattle raising has long been the traditional way of life. New penetration roads extending down from the Andes have encouraged colonization along the margins of both of these areas, as have discoveries of petroleum. The remoter areas of the Amazon region are sparsely inhabited by small groups of Indians.



Population density of Colombia.

THE PEOPLE

In Colombia much care has been taken to preserve the linguistic purity of the official language, Castilian Spanish, and there are close ties between the Spanish and Colombian language academies. Spanish spoken in Colombia is nevertheless marked by the presence of numerous Colombianisms, many of which have been accepted by both academies. American English terminology has also made a significant incursion. In addition to Spanish there are more than 180 indigenous languages and dialects belonging to such major linguistic groups as Arawakan, Chibchan, Cariban, Tupi-Guaraní, and Yurumanguí. Yet Indian peoples constitute less than 2 percent of the population, a much lower share than in other Andean countries.

The tri-ethnic character of the population is most pronounced in the coastal departments where the admixture of Africans historically was greatest. Elsewhere mestizos clearly predominate, although official figures are unavailable. The white population has declined, probably to less than 20 percent, mostly of Spanish origin. Unlike most other South American republics, immigration has never been much encouraged in Colombia, although small numbers from the Middle East, non-Iberian Europe, and the Far East have been absorbed into the population.

High post-World War II growth rates peaked in the mid-1960s, declining subsequently to more moderate levels compared to the rest of Latin America, but still high by world standards. The decline appears to have been in part the result of a variety of government programs to reduce fertility, including family planning and educational services. In addition there has been a significant amount of emigration, especially to oil-rich Venezuela and to the United States. This emigration has been a matter of concern to Colombia, both because the loss represents a high proportion of skilled workers and because these often illegal immigrants experience human-rights problems in the countries to which they move. There continues to be a high rate of internal migration from Colombia's rural areas to its cities, partially determined by the search for better wages and living conditions. The rates of growth in parts of the Llanos and the Caribbean coast, however, grew disproportionately high in the late 20th century, suggesting a general migration from the mountains toward the plains. The rapid growth of the cities has been accompanied by serious unemployment.

Increasing internal migration

Religious freedom is guaranteed by the constitution, although more than 95 percent of Colombians are adherents of Roman Catholicism, the official religion. The church is deeply ingrained in Colombian society, usually taking a leading and authoritative role in the community and having great influence in government. The church has not generally been reform-minded, but some elements of liberalization were evident in the late 20th century. The role of Protestant communities is small, as is that of the thinly spread Jewish community. A few Indian tribes in remote areas still follow their traditional religions.

THE ECONOMY

Colombia's economy is dominated by private enterprise, and direct government participation is limited to such enterprises as the ownership of the railways. The government has attempted to foster economic stability and to encourage private enterprise through indirect measures, such as a favourable system of taxation and the extension of credit to new industries. Economic growth was quite substantial through the mid-1900s, but in the later years of the the 20th century inflation and unemployment grew alarmingly as the growth rate declined.

Agriculture is the basis of the Colombian economy, although industrial development since the 1940s has been remarkable. A substantial proportion of the Colombian land is uncultivated because of the prevalence of poor soils and unfavourable climatic conditions. The eastern plains are sparsely inhabited, the Pacific coast is still in forest because of high rainfall, and large areas in the Magdalena Valley remain in open range or are unused.

Resources. In the colonial period the economy was based almost entirely on gold mining, including the robbing of the metal from Indian graves (*guacas*). The Gold Museum in Bogotá possesses the world's finest and largest collection of worked gold, the product of extraordinarily skilled craftsmen. Today the economy is much more broadly based with the exploitation of hydrocarbon fuels, several metals, agricultural products, and manufactured goods for export and home consumption. Regional development organizations, such as the Cauca Valley Corporation, have been established to promote more balanced industrial growth, with emphasis on hydroelectric power development and flood control.

Early importance of gold

Agriculture, forestry, and fishing. The mountainous

Coffee growing on the middle slopes of the Cordillera Central, near Chinchiná, Caldas department.
Victor Englebert

character of much of Colombia's territory, along with the attendant climatic variations of the different vertical zones, allows for the production of an unusually wide range of both tropical and temperate zone crops, from bananas and sugarcane to wheat, barley, and potatoes. Modern agricultural techniques are employed chiefly in those areas where they are adaptable to the topography. Chemical fertilizers are widely used, and large tracts of flatter lands have been placed under irrigation. Many small farmers, especially in the mountains, nevertheless cling to traditional methods of farming.

Importance of coffee

Coffee represents the backbone of the Colombian economy, constituting about half of all legal exports. The country is second only to Brazil in its production. Coffee, a labour-intensive crop, grows best at an elevation of between 3,300 and 6,300 feet. The farms or estates (*fincas*) on which it is produced are concentrated in the central parts of the three Andean ranges; a few are on the slopes of the Sierra Nevada de Santa Marta. Holdings tend to be small. Colombian coffee, which brings premium prices on the world market, traditionally has been grown under nitrogen-fixing leguminous shade trees, but with the introduction of the high-yielding *caturra* variety, plantings have increasingly been made in the open sunlight.

Bananas and plantains rank as important fruit crops. Most of the bananas grown are exported from plantations located in the Urabá region of the Caribbean coast. Sugarcane is a major crop in the warm and temperate zones, but most of the large plantations and processing plants are located on the alluvial lands of the Cauca Valley near Cali. Some of the sugar is exported, but domestic markets consume the bulk of the production.

Corn (maize), the traditional staple of rural peoples, especially those in the mountains, is grown everywhere except in the *páramos* zones. In some areas it is widely consumed as a form of beer called *chicha*. In the cooler highlands of the Nariño plateau and in the Cordillera Oriental, potatoes are a prominent crop. In the lowlands the production of rice has increased rapidly, most of it grown under irrigation. Cassava (yuca) in the *tierra caliente* and wheat on the *páramos* margins are other major food crops. Kidney beans and sorghum are also widely grown.

Cotton and textiles

Locally grown cotton supplies the requirements of the large Colombian textile industry. Other less significant crops are tobacco, sesame, African oil palms, cacao, peanuts (groundnuts), grapes, soybeans, and citrus fruit. Cut flowers are shipped by air freight in substantial volume from large greenhouses on the Sabana de Bogotá.

Stock raising is a major activity and source of wealth, especially in the lowlands. The Sinú and San Jorge river valleys, the savannas of the Atlantic Lowlands, and the Llanos are the regions with most of the beef cattle. Dairying is especially well developed on the high plateaus of the Cordillera Oriental. Poultry raising has expanded as a result of the application of modern techniques.

The rich resource of the forests has not been fully exploited because access roads to them are few. Where forests are accessible, cutting has been heavy and reforestation programs have been implemented both by the government and by private concerns such as paper manufacturers. The lumber industry is in the process of development, and by the late 20th century there were numerous factories for the manufacture of different types of plywood for domestic use and export.

Ocean fishing is little developed for a country that faces on two great seas. The maritime tradition is of minor proportion. River fish constitute the more abundant catch, although stocks have been reduced as a result of pollution and siltation.

Industry. The Instituto de Fomento Industrial (Institute of Industrial Development) has supplied the necessary capital for enterprises too large to be financed by private investment. The institute has invested large sums to strengthen the metalworking industry, to set up automotive assembly plants, to stimulate the construction of railroad cars and fishing vessels, and to encourage the manufacture of paper, vegetable oils, and petroleum derivatives. Despite these developments, the greater part of Colombian industrial activity continues to be carried on by small enterprises that produce consumer goods. An industry that is growing in importance is tourism, which provides much of the country's foreign exchange.

Emphasis on small enterprises

Mining and quarrying. Minerals have since colonial times played a key role in the Colombian economy. Colombia's gold production comes largely from dredges operating in the departments of Antioquia and Chocó. In some areas the gold-bearing gravels also contain silver and platinum. The export of ferronickel was initiated in 1985 from a major ore deposit, Mount Matoso in the upper reaches of the San Jorge River. A large copper deposit is located in western Antioquia. The Cordillera Oriental has long been an important source of rock salt, marble, limestone, and especially Colombia's highly prized emeralds, of which the country is the major world producer. Coal is mined in the Andean region for local markets, but production now centres on the great Cerrejón deposits in La Guajira, recently connected by rail to a new port at the extreme end of the peninsula.

High hopes were held for petroleum development in the early 1900s, but the results were disappointing. With the development of two major petroleum fields in the northern Llanos and in Amazonia, the outlook for growth has improved. Pipelines across the Andes linking these fields to ocean terminals have also raised the export potential. The older fields in the Magdalena River valley and in the Catatumbo River region facing Venezuela still produce

important quantities of petroleum. The industry is controlled as a government monopoly, but foreign concerns are partners in exploration and development. The major refinery is at Barrancabermeja on the Magdalena River.

Growth of manufacturing

Manufacturing. Manufacturing has been slowly increasing its value to the economy, having reached about 20 percent of the gross domestic product by the mid-20th century. The textile industry employs the largest share of workers and contributes a substantial part of the national income. In addition to supplying the national market, the larger concerns also export fabric and yarn. They are concentrated in Medellín. Food processing and chemical production rank with textiles as leading Colombian industries. Industrial chemicals, produced in part to supply the textile industry, have increased steadily in production, and there is also an important output of pharmaceuticals. The integrated iron and steel mill at Paz de Río, in Boyacá department, utilizes local raw materials and supplies a large share of the country's metal needs. Bogotá, Medellín, and Cali, along with the Caribbean coastal cities of Barranquilla and Cartagena, are the principal industrial centres. The interior location of the first three has placed them at a significant disadvantage in both processing of imported materials and producing for export, but the demands of the growing domestic market, coupled with substantial investments by foreign concerns in productive facilities, has enabled them to sustain substantial growth, especially since World War II. Cheap electric power distributed through a national grid has been an important developmental factor.

Finance and trade. The banking system is composed of a central bank, the Banco de la República, and more than 30 general banking institutions, some of which are partly foreign-owned. The Monetary Commission, created by the government in 1963, is the highest authority in matters involving the extension of credit. Such credit is extended through the central bank, which also issues currency, acts as banker for the government and other banks, serves as a guardian and administrator of the country's international reserves, and acts as a clearinghouse.

Foreign trade is concerned principally with the exportation of raw materials and the importation of machinery and manufactured goods. Colombia's single largest trading partner is the United States. Trade with the countries of the European Economic Community is significant, as is trade with neighbouring Andean countries.

Trading partners

Exports consist largely of coffee, crude petroleum and petroleum products, bananas, fresh-cut flowers, chemicals, and cotton. By the 1970s and '80s the illegal trade in Colombian marijuana and cocaine, especially with the United States, had become a major source of income, probably rivaling the value of legal exports. Imports consist mainly of machinery and transportation equipment, chemical products, crude petroleum and petroleum products, base metals and metal products, and paper and paper products.

Transportation. Transportation plays a particularly vital role in Colombia, where the problems of a diverse and difficult terrain are being overcome to unify the country. By far the most important means of surface transportation is the road system, about one-fourth of which is paved. Two parallel trunk roads extend toward the interior from the Caribbean ports, one following the Cordillera Oriental to Bogotá and Santa Marta, the other passing through Medellín, Cali, and Popayán to the Ecuadorian border. A branch from the first leads to Cúcuta and into Venezuela. There is, however, no overland communication with Panama and Central America, the difficult terrain of the Darién Gap, which separates Panama and Colombia, being the only separation in the Pan-American Highway. Road extension and improvement is a priority of the government, for most domestic cargo today moves by truck. Frequent landslides make highway maintenance difficult. One of the most important transverse routes is that linking Bogotá with the Cauca Valley and Buenaventura, the major Pacific port, through the Cordillera Central.

Role of air transport

Perhaps in no other country has air transport played so major a role as in Colombia. The government-controlled Avianca claims to be the oldest commercial airline operating in the Western Hemisphere. Frequent flights link all important cities, reducing travel times inordinately from those on the tortuous, indirect, and slow mountain highways. Most people travel by air in Colombia, which is claimed to have proportionally the highest rate of air travel in the world. The principal international airport is Bogotá's El Dorado, and there are others at Medellín, Cali, Cartagena, Barranquilla, and Isla San Andrés. The last serves the large tourist industry there.

The role of railroads has become increasingly secondary. The standard-gauge lines are owned by the government. The main line is that of the Ferrocarril del Atlántico, which runs north for 600 miles between Bogotá and the seaport of Santa Marta. At Puerto Berrío in the Magdalena Valley the main line connects with another that passes westward through Medellín and on southward to Cali and the port of Buenaventura. This and other regional lines are frequently closed by landslides.

The Magdalena River no longer plays the vital role in transportation that it once did although it still carries some bulk cargo, especially petroleum. Travelers en route to Bogotá in earlier times moved by river boat as far as La Dorada, where the trip to the interior capital continued overland. The Sinú, Atrato, and Meta rivers are also navigable, but these, too, are less used than formerly. Consideration has been given to the possibility of uniting the Caribbean with the Pacific by the construction of a canal between the Atrato and San Juan rivers.

Cargo ships ply the waters of both the Caribbean and the Pacific, which are joined to the north by the Panama Canal. The Caribbean ports of Cartagena, Barranquilla, and Santa Marta have relatively deep water and are equipped with modern port facilities and services. Silt deposited by the Magdalena River at its mouth requires constant dredging to maintain shipping access to the Barranquilla wharves. On the Pacific coast the port of Buenaventura, on a mangrove-lined embayment, is of easy access with modern installations. Tumaco to the south has been marked for development.

GOVERNMENT AND SOCIAL CONDITIONS

Government. Under the constitution of 1886 Colombia is a republic, the public powers of which are divided between the executive, legislative, and judicial branches of government. The president, who may not succeed himself, is elected to a four-year term by universal suffrage. The executive is assisted by a ministerial Cabinet. The bicameral legislature is composed of a senate and a house of representatives, both of whose members are elected by universal suffrage to four-year terms.

Administrative structure

The country is divided for administrative purposes into 23 departments, four intendencies, five commissariats, and one special district, of Bogotá. The departments are headed by governors appointed by the president, and each has an elected legislature. The departments are subdivided into municipalities, which are headed by mayors appointed by the governors. The intendencies of Arauca, Casanare, Putumayo, and San Andrés y Providencia—as well as the commissariats of Amazonas, Guainía, Guaviare, Vaupés, and Vichada—are governed directly by representatives of the central government.

The Colombian political process had its origins during the formation of the republic. For more than 100 years, the two largest political parties—the Liberals and the Conservatives—maintained a struggle for power. In 1957, in order to overthrow the dictatorship of Gustavo Rojas Pinilla, the parties agreed upon a truce that continued for 16 years (see below *History*). In 1974 the country returned to its traditional system of competition between the two leading political parties.

Suffrage is extended to all citizens over the age of 18. Citizens are guaranteed civil rights, including the right to strike, to assemble, and to petition; freedom of the press is also guaranteed. All male citizens between the ages of 18 and 30 may be called for military service.

Education. The educational system includes kindergartens (preschool facilities), primary schools, and secondary schools and other educational facilities that offer training in industry, domestic science, veterinary science, business, nursing, theology, and art. The majority of the

country's universities are located in the capital city. Public institutions of higher learning include the National University of Colombia, the Francisco José de Caldas District University, the Central University Foundation, and the Women's National Pedagogical University—all of which are in Bogotá—as well as universities in such other major cities as Medellín, Barranquilla, Cartagena, Popayán, and Cali. Private universities in Bogotá include the University Foundation of Bogotá, the Xavieran Pontifical University, and the University of the Andes.

Welfare and health. Welfare services date to the 1930s. Social security programs include health and maternity benefits, workers' compensation, and allowances for those unable to work. As in most Latin-American countries housing is in short supply, a problem that is especially serious in large cities, which attract a large migrant class that settles in slums. The Housing Institute deals with the problem, directing the construction of housing for the low-income rural and urban population.

Public health advancements

The Ministry of Public Health seeks to arouse the interest of individual communities in seeking solutions to health problems through independent efforts. Projects include the construction of systems to supply drinking water; public education in the matters of basic sanitation, home maintenance, balanced diet, and personal cleanliness; and the control of industries and organizations whose operations might be hazardous to health. Malaria and dysentery are common health problems in the rural areas, particularly in the poorly drained lowlands. Hookworm is troublesome in the damp environments of the shaded *cafetales,* or coffee plantations. Yellow fever, once of serious concern in the port cities, has been eradicated. Although health conditions have improved, serious problems still exist, especially among the poor and in remote areas. Many health problems are caused by malnutrition.

CULTURAL LIFE

Geography has caused local isolation to be an important factor in Colombian life, and cultural particularism is highly developed. People are often known by the department in which they live, and Antioqueños, Santandereanos, Tolimenses, Nariñenses, Bogotanos, and Boyacanses are recognized by their dress, diet, and speech. The most important social group is that of the Antioqueños, who migrated from Antioquia southward along the Cordilleras Central and Occidental during the 19th century. Numbering almost 5,000,000, the Antioqueños grow about three-fourths of the nation's coffee crop and control much of Colombia's trade, banking, and industry.

Cultural origins. Prior to the arrival of the first Europeans in the 16th century the aboriginal populations of the area that was to become Colombia had achieved impressive levels of cultural development. Because they built largely of wood and occupied a tropical area of generally moderate to high rainfall, they left little evidence of their achievements. All groups had some form of social organization, but except for the Chibcha of the Cordillera Oriental, they were organized in small chiefdoms (*cacigazcos*) under chiefs (*caciques*), whose authority was sharply limited geographically. Agriculture, pottery making, and weaving were all but universal. Some tribes, like the Chibcha, Quimbaya, Tairona, Sinú, and Calima had impressive skills in metalworking (especially goldsmithing), sculpture, and ceramics. The San Agustín culture, centred in the headwaters area of the Magdalena River, left giant anthropomorphic figures carved of stone that have been an enigma for archaeologists. While groups of Caribbean origin were warlike and practiced ritual cannibalism, others from the interior possessed a rich mythology and a religion that upheld ethical standards and norms on questions of private ownership and the prevention of crime.

Pre-Colombian cultures

Until the mid-1970s it was thought that no indigenous group had left any large architectural monuments—such as those erected by the Aztecs, Mayas, or Incas. The excavation, beginning in 1976, of a 1,500-acre city apparently built about AD 900 by the Tairona in the Santa Marta massif, however, marked a turning point in the study of Colombia's prehistory.

The Andean Indians, particularly the Chibcha, practiced sedentary agriculture and were able to offer but small resistance to the Spanish invaders. Instead, they became the great biological and cultural contributors to the process of racial amalgamation, or *mestizaje.* The low demographic density of the pre-Hispanic population, its swift destruction, and the relatively limited African immigration to Colombia led to the formation of a rather open society and to the substitution of Hispanic forms of culture for the indigenous ones. Since the 17th century the most widely used native language, Chibcha, has virtually disappeared.

Since colonial times, Bogotá—the Athens of South America—has been the nation's cultural centre, and most cultural institutions are located within the metropolitan area. Other cities of cultural importance include Cali, Medellín, Manizales, and Tunja.

The arts. The arts in Colombia are fostered and developed by conservatories and schools that function in several cities either in connection with the universities or independently and by the growing number of concert halls and galleries. Persons of middle income levels display considerable curiosity and the desire to be informed about contemporary artistic developments, and this same eclectic spirit is found among the artists themselves. There is no distinct national school of art.

Literature

The Nobel Prize for Literature awarded to Gabriel García Márquez in 1982 provided recognition of a national literary tradition that Colombians believe constitutes a basic element of the national character, as they boast that more poets than soldiers have occupied the presidency. Although historical themes dominated the earliest writing, the novel and poetry appeared in early colonial times. The European Enlightenment brought essays and the first scientific surveys in the 18th century; political and imaginative themes characterized the 19th century. Although poetry and the novel have remained strong in the 20th century, the focus has often been regional rather than national, personal as much as social.

Handicrafts suffered a decline during the colonial period and into the early years of the republic but since the early 1930s have experienced a revival, especially in the production of textiles. There was also a revival in the manufacture of ceramics and pottery, chiefly in the municipalities of Ráquira, El Espinal, and Malambo. Basket weaving, harness making, and passementerie (fancy edging or trimming on clothing or upholstery) are also popular.

Popular traditions concerning manners and customs, music, legends, and food preparation continue in somewhat attenuated form in their places of origin. Perhaps the most deeply rooted folkloric form of expression is that of music. The tunes and melodies of the indigenous tribes are sung only in limited geographical areas. The music of the mestizo can be divided into that of the Andes, the plains, and the Atlantic Lowlands and the Pacific coast. Some music forms of the colonial period also have survived.

Cultural institutions. The history and culture of Colombia's indigenous peoples are revealed in several museums of outstanding reputation. The Gold Museum of Bogotá contains a famous collection of goldwork, while the Bogotá Museum of Colonial Art has a rich collection of criollo (*i.e.,* by Spanish persons born in Colombia) religious sculpture and painting. The National Museum displays treasures and relics dating from prehistoric times to the present and possesses various collections of Colombian painting and sculpture. The July 20 Museum contains precious documents of the period of independence.

Major museums

No less important vehicles for the diffusion of culture are the National Library and the Bank of the Republic Library, which contains a vast amount of reading material, exposition and music halls, and a concert theatre. Outside Bogotá there are other institutions of this kind, including the Zea Museum in Medellín, and the House of Don Juan de Vargas, in Tunja.

Recreation. Since the 1960s regional fairs have been held in various parts of the country to celebrate occurrences of local importance. They are government-subsidized and, with the aid of modern means of communication, have promoted and preserved popular tunes and dances as well as traditional costumes. Fiestas in Colombia vary locally, but the pre-Lenten carnival is especially celebrated nation-

ally, reaching a particular intensity along the Caribbean coast, especially in Barranquilla.

Sports

Organized sports have grown steadily in popularity among the Colombians. Without question the most widely played and watched sport is football (soccer). Basketball and baseball draw an increasing number of fans, and golf, tennis, and skiing are enjoyed by the smaller numbers who can afford them. Automobile and bicycle racing are also attractions. Perhaps the only indigenous sport is *tejo*, a game similar to quoits, which was derived from the Chibcha Indians. Colombians seem peculiarly to enjoy gambling, including government-sponsored lotteries, which fund social programs. Like many other Latin-American peoples, Colombians enjoy bullfights, an inheritance of their Spanish culture.

Press and broadcasting. Although freedom of the press has generally been established in Colombia, the degree to which the press can exercise its rights has been somewhat dependent upon the government in power. Newspapers have traditionally been the most widely available source of political information and have been the least controlled, while radio and television, regarded more as entertainment media, have received stricter government control. Newspapers have often been the voices of particular political parties; two noted Bogotá newspapers, *El Tiempo* and *El Espectador*, for instance, have usually been identified with the Liberal Party philosophy.

For statistical data on the land and people of Colombia, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR. (C.Ga./Ja.J.P.)

History

PRECONQUEST

Even before the Spanish conquest, the western mountainous part of Colombia attracted the bulk of the population. The higher Indian cultures were found in this region, and the most favourable location for the growth of civilization was the high plateau in the Cordillera Oriental of the Colombian Andes. The present capital city of Bogotá is located near the southern terminus of the plateau, which extends northward to the mountains dividing it from the drainage of the César River. There the Spanish found the major concentration of the Chibchan-speaking peoples.

Pre-Columbian civilization

At the time of the Spanish conquest the Chibcha were in the process of consolidation by warfare. They had not achieved firm union and political institutions, and their other cultural traits had not attained the solidity and refinement needed to resist cultural conquest.

Except for the invading Carib peoples in the deep mountain valleys, there was a considerable similarity among the Chibcha, sub-Andean, and circum-Caribbean cultures of Colombia. All were characterized by intensive agriculture, fairly dense populations living in villages, organized religion, class divisions, and matrilineal inheritance of political and religious offices. The sub-Andean culture in the Cordillera Central and the narrower portions of the Cauca Valley generally lacked the feature of large villages because of the unsuitability of the terrain. The more advanced Chibcha made war for political ends, using large forces armed with the dart and dart thrower.

Geographic and climatic conditions placed limits to the development of the Chibcha and other cultures in Colombia. Of the total Indian population at the time of the conquest, probably about one-third were Chibcha. None of the larger domesticated animals and their wild related species found in the central Andes existed in Colombia. The Chibcha were adequate craftsmen, but their work shows more interest in utility or in the expression of ideas than in the attainment of the skilled workmanship striven for among some sub-Andean peoples.

CONQUEST

European exploration of the Colombian coastline was the work of Rodrigo de Bastidas, who in 1500–01 sailed the Caribbean coast from Cabo de la Vela to Nombre de Dios in Panama, and of Francisco Pizarro, who sailed the Pacific coast in 1525. Effective conquest of Colombia began in 1525 with the founding of Santa Marta on the north coast by Bastidas. In 1533 Pedro de Heredia founded Cartagena, which became one of the major naval and merchant marine bases of the Spanish empire. By the end of 1539 all but one of the major inland colonial cities had been founded, as well as the most important communications centres along the routes connecting them. The capital city of Santa Fé de Bogotá was founded by Gonzalo Jiménez de Quesada in 1538. By mid-century the era of the conqueror drew to an end.

COLONIAL PERIOD

The audiencia. Establishment of the audiencia (an administrative and judicial tribunal) of Santa Fé de Bogotá in 1549 opened the colonial era. The conquerors had organized local governments in accordance with the terms of their contracts with the crown. The crown then rapidly repossessed the broad powers granted the conquerors and formed its own institutions to rule the empire. The governments of Popayán, Antioquia, Cartagena, Santa Marta, Ríohacha, the New Kingdom of Granada (Bogotá), and the llanos of Casanare and San Martín were made subject to the new audiencia. The president of the audiencia was the executive head of government, subject to the viceroy of Peru in administrative matters. The difficulties of travel, however, impeded communications and checked centralized control. The area declined in population after the conquest as a result of disease and the economic demands made upon the Indians.

Dominance of the crown

As elsewhere in the empire, the downward trend seems to have reversed itself at the end of the 17th and the beginning of the 18th century. Acculturation and intermarriage rapidly destroyed most of the special cultural traits of many remaining Indians. Subordinate political jurisdictions developed strong regional characteristics as a result of isolation, which fostered intense local loyalties and rivalries. The economy was based on mining and agriculture, but a small yet important textile industry had grown up in Socorro, north of Bogotá, by the mid-18th century. Slavery was introduced during the conquest and became common in the placer-mining areas of the Chocó and western Antioquia and in the agricultural regions of the Cauca Valley, the lower Magdalena Valley, and the coastal lowlands. Indians were subject to the encomienda tribute, but by 1700 most of the privately held encomiendas had reverted to the crown, and they were rarely granted thereafter. During the era of the audiencia, from 1549 to 1740, the population was politically quiet. The Roman Catholic Church played an important role, providing most welfare services and operating most schools. The church was an effective instrument of the crown, since the latter controlled much of its activity.

Role of the Roman Catholic Church

Viceroyalty of New Granada. Creation of the Viceroyalty of New Granada, which included present-day Colombia, Venezuela, and Ecuador, temporarily in 1717–23 and permanently in 1740, opened a new era. In the next decades the crown introduced political and economic measures to reorganize and strengthen the empire by greater centralization of authority, improved administration and communication, and freer development and movement of trade within the empire. Population grew, trade increased, and prosperity touched the colonial subjects. There was a spurt of intellectual activity and the formation of a corps of Creole intellectuals and professional men, many in government positions. The small Creole officer corps came into being when Charles III, then king of Spain, authorized militia defense units in the colonies. A relatively large group of wealthy landowners and merchants constituted the economic community that supported these new groups. Between 1785 and 1810 in New Granada the outlook of the Creole upper and middle groups changed from resistance toward political and economic change introduced by government to a quest for specific changes in imperial policies. Thus in the Comunero Rebellion of 1780–81 the Socorrans opposed change, while in 1809 they proposed new policies leading to the free-enterprise system, the abolition of slavery, restrictions on government, and worldwide freedom of trade.

Change in Creole politics

Educational reforms played an important role in the changing outlook of the Granadines. Archbishop Caballero

y Góngora as viceroy (1782–88) made education one of his main interests. He modernized the program of studies in the schools, opened a school of mines, and initiated the botanical expedition under the able guidance of naturalist José Celestino Mutis. The new institute trained many of the major figures of the independence movement. The 1790s were the decade in which the first newspaper and the theatre were introduced. A new interest in writing developed and intellectual gatherings for discussion were introduced. In 1808 the allegiance of the Granadines to the crown remained unquestioned except for a few individuals. The once warm loyalty of the Creole middle and upper classes, however, was cooling under the pressure of economic interests, scandals in the royal family, and persistent social tension between Creole and European Spaniards.

REVOLUTION AND INDEPENDENCE

The French invasion of Spain in 1808 caused an outburst of loyalty to king and country and excited grave concern for the church. Profound Granadine anxiety over the fate of the empire and conflicting courses of action attempted by colonial and peninsular subjects over control of government during the captivity of the Spanish king Ferdinand VII led to strife in New Granada and to declarations of independence. In 1810 the subordinated jurisdictions in New Granada threw out their Spanish officials, except in Santa Marta, Ríohacha, modern Panama, and present-day Ecuador. The uprising in Bogotá on July 20, 1810, is commemorated as independence day in Colombia. These new governments swore allegiance to Ferdinand VII and did not begin to declare independence until 1811. Idealists and ambitious provincial leaders desired federation. Creole leaders sought to centralize authority over the new governments. A series of civil wars ensued, facilitating Spanish reconquest of the United Provinces of New Granada between 1814 and 1816. A remnant of republican forces fled to the llanos of Casanare, where they reorganized under Francisco de Paula Santander, a Colombian general who remained a prominent figure in Granadine politics until his death in 1840.

Bogotá uprising

Any remaining loyalty to the crown was alienated by the punitive arbitrary conduct of the European and partisan troops. Their conduct gave validity to the attack on Spanish civilization that began late in 1810 and continued through the 19th century. The forces in Casanare joined those of Simón Bolívar in the Orinoco Valley of Venezuela. By 1819 arrangements for a regular government were completed, and a constitutional convention met at Angostura (now Ciudad Bolívar, Venezuela) with delegates from Casanare and some Venezuelan provinces. In that same year Bolívar invaded New Granada and decisively defeated the Spanish forces on August 7 at Boyacá. There followed the decisive Battle of Carabobo, Venezuela, in 1821 and that of Pichincha, Ecuador, in 1822. Mopping-up operations were completed in 1823, while Bolívar led his forces on to Peru.

Congress of Angostura

The Congress of Angostura laid the foundation for the formation of the Republic of Colombia (1819–30), which was generally known as Gran Colombia because it included what are now the separate countries of Colombia, Venezuela, and Ecuador. The republic was definitively organized by the Congress of Cúcuta in 1821. Prior to that time the government was highly military and strongly centralized with direct executive power exercised by regional vice presidents while President Bolívar was campaigning. Organized as a centralized representative government, the republic had Bolívar as president and acting president Santander as vice president.

Gran Colombia had a brief, virile existence during the war. Subsequent civilian and military rivalry for public office and regional jealousies led in 1826 to a rebellion in Venezuela led by Gen. José Antonio Páez. President Bolívar returned from Peru to restore unity but secured only the acknowledgment of his personal authority. As discontent spread it became clear that no group loved the republic enough to fight for its existence. By 1829 Bolívar had divided the land into four jurisdictions under Venezuelan generals possessing civil and military authority. Meanwhile the convention of Ocaña had failed to reorganize the republic, and the brief dictatorship of Bolívar (1828–30) had no better success. Bolívar then convoked the Convention of 1830, which produced a constitution honoured only in Nueva Granada (Colombia). During this convention Bolívar resigned and left for the northern coast, where he died near Santa Marta on Dec. 17, 1830. By that time Venezuela and Ecuador had seceded from Gran Colombia. Nueva Granada, a country of 1,500,000 inhabitants in 1835, was left on its own (Colombia continued to exercise control over Panama until 1903).

THE REPUBLIC TO 1930

Santander, the vice president under Bolívar and then leader of the opposition to Bolívar's imperial ambitions in 1828, held the presidency from 1832 until 1837 and was the dominant political figure of that era. The 1830s brought some prosperity to the new nation, but a civil war that broke out in 1840 ended a nascent industrial development, disrupted trade, and discouraged local enterprise. The seeds of political rivalry between liberals and conservatives had already been sown, and they bore fruit in the bloody revolution and costly violence that ravaged the country in the years between 1840 and 1903.

Revolution and violence, 1840–1903

Conservative–Liberal struggle, 1840–80. Colombia's modern political history began in the late 1840s with the delineation of the Liberal and Conservative parties. Gen. Tomás Cipriano de Mosquera, a Conservative, during his first term as president (1845–49), replaced the government monopoly on tobacco sales with a private monopoly and expanded international trade. These changes increased the production and export of tobacco but reduced the tax income of the national government.

In 1849 Gen. José Hilario López, of the radical faction of the Liberal Party, became president. It later became his task to implement the reforms passed in 1850, which were to galvanize political sentiment and divide the country politically and economically for half a century. The guiding principle of the radical Liberals under General López was greater liberty for the people of Colombia. His government ended slavery, ended communal ownership of Indian lands, diverted tax resources from the central to local governments, and eliminated a number of taxes and monopolies held by the central government.

Reforms of 1850

Rather than eliminating the institutional barriers to self-fulfillment by the people, however, the reforms of 1850 tended to eliminate the traditional proscriptions that had stood as safeguards against the exploitation of the poor by the rich. The reforms, despite the liberal rhetoric that accompanied them, legalized, indeed encouraged, a redistribution of landed property and tended to strengthen the position of the wealthy landowners, merchants, and professionals against the mass of poor Indians, peasants, and artisans. Since there were only 25,000 slaves (in a

country of 2,000,000 in 1851), the effects of manumission were small compared to those of the breakdown of the Indian communal system, which affected a third of the population. The Indians were induced to give up their little plots of land and the small amount of independence they enjoyed. Within a few years the ownership of Indian lands was concentrated in a few hands; the Indian had become a tenant, his land used for grazing cattle.

But while class conflict seethed under the surface in Colombian society, the struggle between members and groups within the elite was more open. Two issues in particular divided the upper class: first, whether a centralist or federalist political system would be the best arrangement for Colombia, and second, what role was appropriate for the Roman Catholic Church and particularly for its clerics in Colombian society. Adherents of federalism were strongest in the years between 1863 and 1880, during which years the country was called the United States of Colombia. Subsequent government publications were to refer to that period as the "Epoch of Civil Wars." In 51 of the 240 months that passed in the 1860s and '70s, there was some form of civil conflict taking place within the country. The Colombian army was so small that public order could not be maintained.

The "Epoch of Civil Wars"

The power of the anticlerical faction reached a peak in the early 1860s. A revolutionary government headed by Mosquera expropriated church lands in 1861, and a constitution adopted in 1863 guaranteed freedom of religious practice, thus bringing to an end the traditional intimate relationship between church and state in Colombia.

The return of the Conservatives, 1880–1930. Both actions were reversed during the period of Regeneration (1880–95) under Rafael Núñez and the Conservatives who followed him. After further civil conflict in the 1880s Núñez was able to promulgate a new constitution in 1886, to reestablish relations with the Vatican via the Concordat of 1887, and to promote some internal improvements and industrial development. But the political struggle between Liberals and Conservatives was far from over. Armed conflict reached its peak in the War of a Thousand Days (1899–1903). The estimates of the number of deaths in that struggle range from 60,000 to 130,000.

The tragedy of civil war was followed by the loss of Panama. The Colombian Congress vacillated too long in considering a United States offer to build a canal across the isthmus, and in 1903 the Panamanians revolted against the government in Bogotá and arranged for a treaty agreement providing for U.S. sovereignty in the 10-mile-wide Canal Zone in exchange for an agreement by the United States to build the canal and to provide a regular annual payment to Panama. Although the U.S. government later agreed to pay $25,000,000 to Colombia, the episode embittered Colombian-U.S. relations for many years.

Colombia's internal development quickened after 1905, with coffee exports expanding by nearly 10 percent per year between 1909 and 1928. At the beginning of the 20th century Colombia supplied about 3 percent of world coffee exports; by 1923 its share had risen to nearly 10 percent. In the late 1920s coffee accounted for some 18 percent of the gross domestic product.

Colombia's internal development

COLOMBIA SINCE 1930

The new dependence on exports was not without its pitfalls. In the late 1920s coffee, petroleum, and bananas accounted, respectively, for 69, 17, and 6 percent of total Colombian exports, and all three dropped precipitously in value during the Great Depression. This economic collapse had an immediate political result; the Conservatives were ousted from the presidency by Enrique Olaya Herrera (who served 1930–34).

The era of the Liberals, 1930–46. During the presidency of Alfonso López, from 1934 to 1938, a series of reforms, called the "Revolution on the March," was instituted. The most important social act of the López regime established effective occupancy as the legal basis for tenure (1936), thus upholding the rights of thousands of peasant squatters against the claims of landowners who had been holding land without using it productively. In the coffee-growing zone of Cundinamarca, west of Bogotá, thousands of families obtained recognition of their ownership by occupation. Subsequent governments took a more conservative stance toward the question of land rights of the poor, but in 1961 continuing social pressure finally resulted in legislation to create the Colombian Institute of Agrarian Reform (Instituto Colombiano de Reforma Agraria). By the mid-1970s, more than 135,000 land titles had been distributed by the institute.

Rapid industrial development started in the 1930s. Medellín became the principal producer of cotton textiles and other fabrics. The limited availability of imports because of the Depression enabled local manufacturing to get its start. The tendency toward substitution of home products for imports continued into the 1950s and 1960s, when Colombia became practically self-sufficient in production of consumer nondurables. By the early 1980s, however, manufacturing still accounted for the same one-fifth of the gross domestic product that it had in the early 1960s.

Civil unrest, dictatorship, and democratic restoration, 1946–70. Liberal hegemony continued through the 1930s and the World War II era. In the elections of 1946, however, two Liberal candidates, Gabriel Turbay and Jorge Eliécer Gaitán, stood for election and thus split the Liberal vote. A Conservative, Mariano Ospina Pérez, took office, and Conservatives instituted crude reprisals against Liberals. On April 9, 1948, Gaitán, leader of the left wing of the Liberal Party, was assassinated in broad daylight in downtown Bogotá. The resulting riot and property damage (estimated at $570,000,000 for the country as a whole) has come to be called the *bogotazo*.

Conservative resurgence

There is disagreement on whether the acts of violence began in 1930 when the Liberals came to power, in 1946 with the Conservatives, or in 1948 with the death of Gaitán. There is agreement that they sprang from a political feud between Liberals and Conservatives that had little to do with class conflict, foreign ideologies, or other matters extraneous to the Colombian scene. Authoritative sources estimate that some 200,000 persons lost their lives in the period known as La Violencia, between 1948 and 1962. The most spectacular aspect of the violence, however, was the extremes of cruelty perpetrated on the victims. The aggressive force unleashed by that political conflict has been a continuing problem of study for Colombians.

La Violencia

La Violencia intensified under the regime of Laureano Gómez (1950–53), who attempted to introduce a fascist state. His excesses brought his downfall by military coup—Colombia's first in the 20th century. Gen. Gustavo Rojas Pinilla assumed the presidency in 1953 and, aided by his daughter, María Eugenia Rojas, began an effort to end La Violencia and to stimulate the economy. Rojas was a populist leader who appealed to the masses and supported their call for the redress of grievances against the elite. Support for Rojas began to collapse when it appeared that he would not be able to fulfill his promises and when the economy faltered as a result of a disastrous fall in coffee prices in 1957. Rojas was driven from office in 1957 by a military junta.

The arrangement for the National Front (Frente Nacional) government—a coalition of Conservatives and Liberals—was made by Alberto Lleras Camargo, representing the Liberals, and Laureano Gómez, leader of the Conservative Party, in the Declaration of Sitges (1957). The unique agreement provided for alternation of Conservatives and Liberals in the presidency, an equitable sharing of ministerial and other governmental posts, and equal representation on all executive and legislative bodies. The agreement was to remain in force for 16 years—equivalent to four presidential terms, two each for Conservatives and Liberals. The question of what governmental structure would follow the National Front was left unsettled.

Terms of the National Front

It had been contemplated that a Conservative would be the first to occupy the presidency in 1958. When the Conservative Party could not agree on a candidate, however, the National Front selected Lleras Camargo, who had previously served in that office for 12 months in 1945–46. During Lleras Camargo's tenure an agrarian reform law was brought into effect, national economic planning for development got its start, and Colombia became the showcase of the Alliance for Progress (a U.S. attempt to further

economic development in Latin America). But severe economic difficulties were caused by low coffee prices and domestic unemployment. The Alliance increased Colombia's economic dependence on the United States, which, to some Colombians, had serious disadvantages. By 1962 economic growth had come almost to a standstill.

The degree of social tension was revealed when only about half of those eligible to vote did so in the 1962 presidential elections, which brought Guillermo León Valencia, a Conservative, to the presidency. During Valencia's first year in office internal political pressures led to devaluation of the peso, wage increases among unionized workers of some 40 percent, and the most rampant inflation since 1905. Extreme deflationary policies were applied in the next three years, raising the unemployment rates above 10 percent in the major cities and turning even more Colombians against the National Front. Less than 40 percent of the electorate voted in the 1964 congressional elections. Marxist guerrillas began appearing in Colombia during Valencia's presidency, including the National Liberation Army (Ejército de Liberación Nacional) and the Colombian Revolutionay Armed Forces (Fuerzas Armadas Revolucionarias de Colombia).

Government of Lleras Restrepo

Carlos Lleras Restrepo was the third National Front president (1966–70). He returned the economy to a sound footing and pushed through political reforms essential to an orderly end to the National Front (which seemed increasingly to constitute a monopoly of power by the Conservative–Liberal oligarchy). Semiautonomous government corporations expanded their services to the private sector: the capital and reserves of the Institute of Industrial Development (Instituto de Fomento Industrial), for example, were increased more than ten-fold during 1967. Colombia achieved its best rate of economic growth near the end of the Lleras administration, when the real gross domestic product increased by some 7 percent. These successes were in part due to high coffee prices, as well as government policy.

In the 1970 presidential election Misael Pastrana Borrero, the Conservative candidate backed by the National Front, nearly lost to former dictator Gustavo Rojas Pinilla because the urban vote went strongly against the Front. (For the first time Colombia's population was more than 50 percent urban. A rapid migration from country to city created new urban interest groups—particularly in the lower middle and working classes—that felt unrepresented by the traditional parties.) Nonetheless, the traditional parties prevailed and were not again successfully challenged.

The Conservative–Liberal rule. The process of change brought with it new political, economic, and social problems, stemming from uneven development, unequal gains, and a growing perception that the benefits of higher income on average were not widely shared. The transition from National Front to moderate political competition between Liberals and Conservatives in 1974 was reasonably smooth. Alfonso López Michelsen of the Liberal Party served his four-year term as president (1974–78) and handed power to Julio César Turbay Ayala, a centrist Liberal. Low rates of voter participation continued, keeping alive fears that military alternatives to democratic elections might be sought from the right or the left. In 1982, however, the Liberal vote was split, and Belisario Betancur Cuartas, the Conservative candidate, was elected president.

The presidency of Betancur was marred by violence that tested Colombia's long-term commitment to democracy. Terrorists kidnapped and held captive a number of foreign ambassadors, and, in 1984, extremists believed to be linked to the international drug trade assassinated the minister of justice. In 1985, guerrillas entered the Palace of Justice in Bogotá and held a number of captives before being expelled by military personnel with a loss of life estimated at roughly 100, including several Supreme Court judges. These events indicated growth in the power of drug traffickers and an apparent inability of the government to control terrorist activities. (W.P.McG.)

The presidency of Virgilio Barco Vargas, a former mayor of Bogotá, began in August 1986 with hopes for improving civil order and reversing the long-term decline in the rate of economic growth. However, guerrilla attacks became more commonplace, and paramilitary groups caused even more deaths than the leftist insurgents. Drug cartels, especially that of Medellín, also began using terror to increase their bargaining power with the government. As a result, homicide became the leading cause of death in the country, and 1989 was the most violent year in Colombia's history, with more deaths per capita from violence than during any year of La Violencia.

The discovery in 1985 of a large petroleum reserve provided a major economic boost. Ironically, the drug trade was at times an economic asset, making annual trade balances positive when they were negative for legal goods. Further, as drug dealers became wealthier, they spent money refining cocaine, organizing groups for protection, and constructing buildings (both residential and commercial).

In 1990 drug traffickers killed three presidential candidates, including the poll-leading Liberal Luis Carlos Galán, and hundreds of other people. Despite threats of terrorism, however, about half of the electorate voted in the peaceful May election, which was won by former finance minister and hard-line anti-drug candidate César Gaviria Trujillo of the Liberal Party. Gaviria negotiated with rebel leaders, struck plea-bargain agreements with drug cartel chiefs, and called a constitutional assembly, which replaced the 1886 document with the constitution of 1991.

The constitution of 1991

The constitutional changes were significant, at least on paper. Presidents, who were limited to one term, were to be elected by an absolute majority, with a second-round vote if necessary. The Senate was to be elected by a national constituency, which in theory gave minority parties a chance to elect a senator with only 1 percent of the vote. New electoral rights (including initiative and recall) were instituted, and a new National Prosecutor's Office (Fiscalía) was set up to make the Colombian prosecutorial system more like that of the United States.

The Gaviria government continued the economic opening begun by Barco. In keeping with the neoliberal mood throughout Latin America, Colombia lowered tariffs on imports, removed subsidies for the poor, and limited the government's role in the economy.

Gaviria's negotiations with the guerrilla groups yielded no agreements. Plea bargaining did lead to the surrender of most leaders of the Medellín cartel, although the most notable one, Pablo Escobar, escaped after only 13 months in jail. (He was subsequently killed by government forces following an extensive manhunt.)

The 1994 presidential election was won in the second round by Ernesto Samper Pizano, a Liberal, over Conservative Andrés Pastrana. During the Samper presidency the leaders of the Cali cartel surrendered and were tried and sent to jail. However, Samper's presidency was tainted by Pastrana's accusation that Samper had bargained with the Cali drug cartel for campaign contributions. Violence increased, and the paramilitary groups founded a national organization. The 1998 election was won by Pastrana, who soon faced a severe economic downturn. Pastrana also renewed negotiations with rebel groups and granted them de facto control over a large portion of the southern state of Caquetá. In 2000 the U.S. Congress approved a controversial aid program, which provided military assistance to help control the cocaine trade. (Ed.)

Biological Coloration

Biological coloration is the general appearance of an organism as determined by the quality and quantity of light that is reflected or emitted from its surfaces. Coloration depends upon several factors: the colour and distribution of the organism's biochromes (pigments), particularly the relative location of differently coloured areas; the shape, posture, position, and movement of the organism; and the quality and quantity of light striking the organism. The perceived coloration depends also on the visual capabilities of the viewer. Coloration is a dynamic and complex characteristic and must be clearly distinguished from the concept of "colour," which refers only to the spectral qualities of emitted or reflected light.

Many evolutionary functions have been suggested for the effects of coloration on optical signaling. An organism with conspicuous coloration draws attention to itself, with some sort of adaptive interaction the frequent result. Such "advertising" coloration may serve to repel or attract other animals. While conspicuous coloration emphasizes optical signals and thereby enhances communication, coloration may, conversely, suppress optical signals or create incorrect signals and thereby reduce communication. This "deceptive" coloration serves to lessen detrimental or maladaptive interactions with other organisms.

Coloration may also affect an organism in ways other than its interaction with other organisms. Such nonoptical functions of coloration include physiological roles that depend on the molecular properties (*e.g.,* strength and type of chemical bonds) of the chemicals that create colour. For example, dark hair is mechanically stronger than light hair, and dark feathers resist abrasion better than light feathers. Coloration may also play a part in the organism's energy budget, because biochromes create colour by the differential reflection and absorption of solar engery. Energy absorbed as a result of coloration may be used in biochemical reactions, such as photosynthesis, or it may contribute to the thermal equilibrium of the organism. Nonoptical functions of coloration also include visual functions in which coloration or its pattern affects an animal's own vision. Surfaces near the eye may be darkly coloured, for instance, to reduce reflectance that interferes with vision.

Emitted light, the product of bioluminescence, forms a portion of the coloration of some organisms. Bioluminescence may reveal an organism to nearby animals, but it may also serve as a light source in nocturnal species or in deepwater marine animals such as the pinecone fishes (*Monocentris*). These fishes feed at night and have bright photophores, or bioluminescent organs, at the tips of their lower jaws; they appear to use these organs much like tiny searchlights as they feed on planktonic (minute floating) organisms.

Because many pigments are formed as the natural or only slightly modified by-products of metabolic processes, some coloration may be without adaptive function. Nonfunctional coloration can, for example, be an incidental effect of a pleiotropic gene (a gene that has multiple effects), or it can result from pharmacological reaction (as when the skin of a Caucasian person turns blue in cold water) or from pure chance. It seems unlikely, however, that any apparently fortuitous coloration could long escape the process of natural selection and thus remain totally without function.

Regardless of its adaptive advantages, a particular coloration or pattern of coloration cannot evolve unless it is within the species' natural pool of genetic variability. Thus a species may lack a seemingly adaptive coloration because genetic variability has not included that coloration or pattern in its hereditary repertoire.

Because humans are highly visual animals, we are naturally interested in and attentive to biological coloration. Human attention to coloration ranges from the purely aesthetic to the rigidly pragmatic. Soft, pastel colorations aid in increasing work efficiency and contribute to tranquil moods; bright, strongly contrasting colours seem to contribute to excitement and enthusiasm. These phenomena may be extensions of the basic human response to the soft blue, green, and brown backgrounds of the environment as opposed to sharply contrasting warning colorations found on many dangerous organisms. It is possible that much of the aesthetic value humans attach to coloration is closely related to its broad biological functions.

Human interest in coloration has led to biological studies. The classical work by the Moravian abbot Gregor Mendel on inherited characteristics, based largely on plant coloration, formed the foundation for modern genetics. Coloration also aids in the identification of organisms. It is an easily perceived, described, and compared characteristic. Related species living in different habitats, however, frequently have strikingly different colorations. Since coloration is susceptible to alteration in various functional contexts, it usually lacks value as a conservative characteristic for determining systematic relationships between all but the most closely related species.

Related articles of interest include BEHAVIOUR, ANIMAL; MIMICRY. (G.S.Lo./E.H.B.)

This article is divided into the following sections:

Structural and biochemical bases for colour

Organisms produce colour physically, by submicroscopic structures that fractionate incident light into its component colours (schemochromes); or chemically, by natural pigments (biochromes) that reflect or transmit (or both) portions of the solar spectrum. Pigmentary colours, being of molecular origin, may be expressed independently of structural colour and are not altered by crushing, grinding, or compression. Structural colours are often reinforced by the presence of biochromes and are altered or destroyed by crushing, grinding, or compression.

STRUCTURAL COLOURS (SCHEMOCHROMES)

The physical principles of total reflection, spectral interference, scattering, and, to some extent, polychromatic diffraction, all familiar in reference to inanimate objects, are also encountered among tissues of living forms, most commonly in animals. In plants these physical principles are exemplified only by the total reflection of white light by some fungi and bacteria and by the petals of some flowers and barks, and by some spectral interference in certain sea plants.

Reflection. Total reflection of light—which imparts whiteness to flowers, birds' feathers, mammalian hair, and the wings of certain butterflies—often results from the separation of finely divided materials by minute air spaces. Secretions or deposits in tissues may also contribute to the whiteness; for example, the fat and protein in mammalian milk and the calcium carbonate in the shells of mollusks, crustaceans, certain echinoderms, corals, and protozoans.

Iridescent colours

Interference. Fractionation of white light into its components occurs in organisms (chiefly animals) through interference: the incident light penetrates the animal structure and is reflected back through successive ultrathinly layered films, giving striking iridescence, even in diffuse light, as a result of the asynchrony between the wavelengths of visible light that enter and those that return.

Brilliant interference colours may display variety or be predominantly of one kind, depending upon the relative thicknesses of layers and interlaminar spaces giving rise to the colours. Such colours also are changeable with the angle of vision of the viewer.

Purely prismatic refraction of light (sometimes confused with interference iridescence) is probably rare in animals and is limited to instances in which direct beams of light impinge upon certain microcrystalline deposits. Polychromatic diffraction—*e.g.,* by natural, fine gratings or regular fine striations—may be observed among certain insects, but, like prismatic refraction, it is conspicuous only when a direct beam of light strikes such structures and they are viewed at an angle.

Scattering. A special instance of diffraction, often referred to as the Tyndall effect (after its discoverer, the 19th-century British physicist John Tyndall), results in the presence of blue colours in many animals. The Tyndall effect arises from the reflection of the shorter (blue) waves of incident light by finely dispersed particles situated above the dark layers of pigment, commonly melanin deposits. In these blue-scattering systems, the reflecting entities—whether very small globules of protein or lipid, semisolid substances in aqueous mediums, or very small vesicles of air—are of such small size as to approximate the shorter wavelengths of light (about 0.4 micron). The longer waves, such as red, orange, and yellow, pass through such mediums and are absorbed by the dark melanin below; the short waves, violet and blue, encounter bodies of approximately their own dimensions and consequently are reflected back.

Origin of Tyndall effect in animals

Two types of coloration may act in combination; in some instances, for example, structurally coloured and pigmented layers may be superimposed. Most of the greens found in the skin of fishes, amphibians, reptiles, and birds do not arise from the presence of green pigments (although exceptions occur); rather, they result from the emergence of scattered blue light through an overlying layer of yellow pigment. Extraction of the yellow pigment from the overlying cuticle of a green feather or of a reptilian skin leaves the object blue. (D.L.F./E.H.B.)

PIGMENTS (BIOCHROMES)

Plants and animals commonly possess characteristic pigments. They range in plants from those that impart the brilliant hues of many fungi, through those that give rise to the various browns, reds, and greens of species that can synthesize their food from inorganic substances (autotrophs), to the colourful pigments found in the flowers of seed plants. The pigments of animals are located in nonliving skin derivatives such as hair in mammals, feathers in birds, scales in turtles and tortoises, and cuticles and shells in many invertebrates. Pigments also occur within living cells of the skin. The outermost skin cells may be pigmented, as in humans, or special pigment-containing cells, chromatophores, may occur in the deeper layers of the skin. Depending on the colour of their pigment, chromatophores are termed melanophores (black), erythrophores (red), xanthophores (yellow), or leucophores (white). (F.A.B.)

Chemical and biochemical features. The colour of a chemical compound depends on the selective absorption of light by molecules whose size or vibrational wavelengths or both lie between 3000 and 7000 angstroms (one angstrom equals 10^{-7} millimetre). Selective absorption of visible light results from retardation in the relative speed or vibrational frequency of the many rapidly vibrating electron pairs found in a compound. Sufficient modification in the frequency of vibration imparts to the whole molecule a special motion, or chemical resonance, that absorbs entering light rays of matching frequency with the evolution of heat; the residual, unabsorbed light is transmitted to the eye.

Selective absorption of light rays

If the molecular resonance involves short, rapid waves, the shorter visible light waves are absorbed (*i.e.,* violet and blue) and the compound appears yellow or orange; red-appearing substances, having slightly longer resonance values, absorb light from the blue and green regions; and blue and green compounds result from cancellation of light in the red or orange realms. Black substances absorb all light equally and completely; white compounds absorb no light in the visible spectrum. The colour reflected by a pigment usually includes all the wavelengths of visible light except the absorbed fraction; the observed colour of a compound thus depends upon the dominant wavelength reflected or transmitted.

The more important natural pigments may be grouped into (1) classes whose molecules lack nitrogen and (2) those that contain nitrogen. Of the nonnitrogenous pigments, by far the most important, conspicuous, and widely distributed in both plants and animals are the carotenoids. Naphthoquinones, anthraquinones, and flavonoids are other nitrogen-free pigments that occur in animals, all being synthesized originally in plants, as are the carotenoids. But unlike the carotenoids, the others have a limited distribution in animals, and little is known of their physiological attributes in either kingdom.

Distinction between nitrogenous and nonnitrogenous pigments

Prominent among the nitrogenous biochromes are the tetrapyrroles, including both the porphyrins (*i.e.,* the red or green heme compounds present in the blood of many animals and the green chlorophylls of many plants) and the bile pigments, which occur in many secretions and excretory products of animals and in plant cells. Equally prominent are the melanins, which are dark biochromes found in skin, hair, feathers, scales, and some internal membranes; they represent end products from the breakdown of tyrosine and related amino acids.

Below are outlined the basic colours, sources, and metabolic features of some representative biological pigments.

Carotenoids. The carotenoids constitute a group of yellow, orange, or red pigments of almost universal distribution in living things. Carotenoids generally are insoluble in water but dissolve readily in fat solvents such as alcohol, ether, and chloroform. They are readily bleached by light and by exposure to atmospheric oxygen and are also unstable in acids such as sulfuric acid.

Carotenoids occur as two major types: the hydrocarbon class, or carotenes, and the oxygenated (alcoholic) class, or xanthophylls. Some animals exhibit a high degree of selectivity for the assimilation of members of one or the

Two basic types of carotenoids

other class. The horse (*Equus caballus*), for instance, absorbs through its intestine only the carotenes, even though its green food contains mostly xanthophylls; the domestic hen (*Gallus domesticus*), on the other hand, stores only members of the xanthophyll class, as do many fishes and invertebrates. Other animals, including certain frogs, *Octopus* species, and humans, assimilate and store both classes in the liver and in fat deposits.

Carotenoids are synthesized by bacteria, fungi, algae, and other plants to highly evolved flowering forms, in which they are most conspicuous in petals, pollen, fruit, and some roots—*e.g.,* carrots, sweet potatoes, tomatoes, and citrus fruits. All animals and protozoans contain carotenoids, although the blood plasma of a number of mammals (*e.g.,* swine, sheep, goats, some carnivores) is almost entirely free of these pigments. The livers of animals often yield carotenoids; all animals depend upon a nutritional supply of vitamin A or one of its precursors, such as carotene, for maintenance of normal metabolism and growth. Carotenoids are relatively more concentrated in such structures as ovaries, eggs, testes (some animals), the liver (or the liver-like analogue of invertebrates), adrenal glands, skin, and eyes. In birds, carotenoid pigmentation may be conspicuous in the yellow tarsal (lower leg) skin, external ear, body fat, and egg yolk (especially in poultry) and in red-coloured feathers. Carotenoids are also found in the wings or wing covers of many insects and in the milk fat of cattle.

Quinones. The quinones include the benzoquinones, naphthoquinones, anthraquinones, and polycyclic quinones.

Benzoquinones. Benzoquinones occur in certain fungi and in roots, berries, or galls (abnormal growths) of higher plants, from which they can be recovered as yellow, orange, red, violet, or darker coloured crystals or solids. Small quantities of pale-yellow crystals of coenzyme Q, often called ubiquinones, are almost universally distributed in plants and animals. The ubiquinones impart no recognizable coloration to an organism because of their very small concentrations; they play an important role, however, as respiratory enzymes in catalyzing cellular oxidations.

Ubiquinones

Naphthoquinones. Naphthoquinones are encountered in some bacteria and in the leaves, seeds, and woody parts of higher plants. They can be recovered as yellow, orange, red, or purple crystals. They are soluble in organic solvents and have been used extensively as dyes for fabrics. Among the naphthoquinones of biochemical and physiological importance are the K vitamins. Another series within the naphthoquinone class manifests conspicuous red, purple, or sometimes green colours in a few animal types. These are the echinochromes and spinochromes, so named because they are conspicuous in tissues and in the calcareous tests (shells) of echinoids, or sea urchins.

Anthraquinones. The anthraquinones occur widely in plants but in only a few animals. These brilliantly coloured compounds have found wide application as dyes and as chemical indicators of acidity or alkalinity.

Polycyclic quinones. The polycyclic quinones occur in some bacteria, fungi, and parts of higher plants. One of the more interesting representatives is the aphin group, so called because of their initial recovery from the hemolymph (circulating fluid) of several coloured species of aphids; aphids parasitize plants, as do the other quinone-assimilating insects.

Flavonoids. The biochromes in the class of flavonoids, another instance of compounds lacking nitrogen, are extensively represented in plants but are of relatively minor and limited occurrence in animals, which rely on plants as sources of these pigments. Flavonoids consist of a 15-carbon skeleton compound called flavone (2-phenylbenzopyrone), in which one or more hydrogen atoms (H) is replaced either by hydroxyl groups (—OH) or by methoxyl groups ($-OCH_3$). Flavonoids occur in living tissue mainly in combination with sugar molecules, forming glycosides. Many members of this group, notably the anthoxanthins, impart yellow colours, often to flower petals; the class also includes the anthocyanins, which are water-soluble plant pigments exhibiting orange-reds, crimson, blue, or other colours.

Anthoxanthins. The variety of anthoxanthins is greater than that of anthocyanins, and new anthoxanthins are continuously being discovered. A prominent flavonoid is the pale-yellow flavonal quercitin, first isolated from an oak (*Quercus*) but widely distributed in nature. A weak acid, it combines with strong acids to form orange salts, which are not very stable and readily dissociate in water. Quercitin is a strong dyestuff; it yields more than one colour, depending on the mordant used. A yellow pigment isolated from the wings of the butterfly *Melanargia galatea* possesses chemical properties closely allied to those of quercitin. Other well-known anthoxanthins include chrysin, found in the leaf buds of the poplar (*Populus*), and apigenin, found in the leaves, stem, and seeds of parsley (*Petroselinum*) and the flowers of the camomile (*Anthemis*).

Quercitin

Anthocyanins. The anthocyanins are largely responsible for the red colouring of buds and young shoots and the purple and purple-red colours of autumn leaves. The red colour becomes apparent when the green chlorophyll decomposes with the approach of winter. Intense light and low temperatures favour the development of anthocyanin pigments. Some leaves and flowers lose anthocyanins on reaching maturity; others gain in pigment content during development. Often an excess of sugars exists in leaves when anthocyanins are abundant. Injury to individual leaves may be instrumental in causing the sugar excess in such cases. Anthocyanins also occur in blossoms, fruits, and even roots (*e.g.,* beets) and occasionally in larval and adult flies and in true bugs (Heteroptera).

A typical anthocyanin is red in acid, violet in neutral, and blue in alkaline solution. Thus, the blue cornflower, the bordeaux-red cornflower, the deep-red dahlia, and the red rose contain the same anthocyanin, the variation in colour resulting from the different degrees of acidity and alkalinity of the cell sap. More than one anthocyanin may be present in a flower or blossom, and the colours of many flowers are caused by the presence of both anthocyanins and plastid pigments in the tissues. Moreover, small genetic changes in varieties or species may be associated with the development of different anthocyanins.

No physiological functions seem to have been definitely established for the flavonoids in animals and plants. It has been pointed out, however, that flower colour is valuable in attracting bees, butterflies, and other pollen-transporting visitors that implement fertilization in plants; brightly coloured fruits have improved seed dispersal by animals attracted to them as food.

Tetrapyrroles, porphyrins, and their derivatives. A biologically important class of water-soluble, nitrogenous 16-membered ring, or cyclic, compounds is referred to as porphyrins. The elementary structural unit of all porphyrins is a large ring itself composed of four pyrrole rings, or cyclic tetrapyrroles. This basic compound is known as porphin.

Porphyrins combine with metals (metalloporphyrins) and protein. They are represented by the green, photosynthetic chlorophylls of higher plants and by the hemoglobins in the blood of many animals.

Porphyrins. Many invertebrates display in their skins or shells porphyrin pigments (or salts of them), some showing fluorescence (*i.e.,* the emission of visible light during exposure to outside radiation). In addition, various porphyrins occur in secretory and excretory products of animals, and some kinds, predominantly the phorbides, which result from the breakdown of chlorophyll, have been recovered from ancient natural deposits such as coal and petroleum and from muds of long-buried marine and lacustrine strata. Ooporphyrin is responsible for the red flecks on the eggshells of some plovers and many other birds. The African turacos (Musophagidae) secrete a copper salt of uroporphyrin III into their wing feathers. This deep-red pigment, turacin, is readily leached from the feathers by water containing even traces of alkali. The green plumes of these birds owe their colour to the presence of turacoverdin, a derivative of turacin.

Porphyrins in secretory and excretory products

Hemoglobins. Hemoglobins are present in the red blood cells of all vertebrate animals and in the circulatory fluids of many invertebrates, notably annelid worms, some arthropods, echinoderms, and a few mollusks. The hemoglobin molecule consists of a heme fraction and a

globin fraction; the former consists of four pyrrole moieties (porphin) with a ferrous iron (Fe^{2+}) atom in the centre. The globin fraction is a protein that may constitute more than 90 percent of the total molecular weight of hemoglobin. Hemoglobins have the capacity to combine with atmospheric oxygen in lungs, gills, or other respiratory surfaces of the body and to release oxygen to tissues. They are responsible for the pink to red colours observed in combs and wattles of birds and in the skin of humans and other primates. Particularly prominent are portions of the face, buttocks, and genital areas of baboons.

Chlorophylls. Chlorophyll is one of the most important pigments in nature. Through the process of photosynthesis, it is capable of channeling the radiant energy of sunlight into the chemical energy of organic carbon compounds in the cell. For a detailed account of this process, see PHOTOSYNTHESIS. A pigment very much like chlorophyll was probably the first step in the evolution of self-sustaining life. Chlorophyll exists in several forms. Chlorophylls *a* and *b* are the chief forms in higher plants and green algae; bacteriochlorophyll is found in certain photosynthetic bacteria.

Types of chlorophyll

The chlorophylls are magnesium porphyrin compounds in which a cyclic tetrapyrrole is attached to a single central magnesium atom. They contain two more hydrogen atoms than do other porphyrins. The various forms differ in minor modifications of side groups attached to the pyrrole groups. In higher plants, chlorophyll is bound to proteins and lipids aschloroplastin in definite and specific laminations in bodies called chloroplasts. The combination of chlorophyll with protein in chloroplastin is of special significance, because only as a result of the combination is chlorophyll able to remain resistant to light.

Linear tetrapyrroles

Bilins. Among the metabolic products of certain porphyrins, including the heme portion of hemoglobin, is a series of yellow, green, red, or brown nonmetallic compounds arranged as linear, or chain, structures rather than in the cyclic configuration of porphyrins. These are the so-called bilins, or bilichromes. Small quantities of the red waste compound, bilirubin ($C_{33}H_{36}O_6N_4$); a green product formed from it by the removal of two hydrogen atoms, biliverdin ($C_{33}H_{34}O_6N_4$); and various other chemically similar compounds occur in normal tissues and may be conspicuous in excretory or secretory materials under normal circumstances and certain pathological conditions. The bile pigments, although first identified in mammalian tissues or products (*e.g.,* in the bile of the gall bladder), are by no means confined thereto. Various members of the bilichrome series are encountered in invertebrates, lower vertebrates, and in red algae and green plants.

Although the bile pigments of animals arise in all probability from the catabolism of heme precursors, there is evidence that bilirubin, accompanied by iron salts, promotes the synthesis of new hemoglobin when injected into humans, dogs, or rabbits suffering from secondary anemia.

In addition to the chlorophylls, plants also contain linear bilichromes, which have especially important roles in green plants. Among them are the blue phycocyanins and the red phycoerythrins, which serve, in red algae, as accessory pigments in photosynthesis. Another example is phytochrome, a bilichrome pigment of blue colour, which, although present in very minute quantities in green plants, is indispensable in various photoperiodic processes.

Types of phytochrome

Phytochrome exists in two alternative forms: P_{660} and P_{730}. Of these, P_{730} triggers the germination and respiration of seeds (and of spores of ferns and mosses), the flowering of long-day plants (or inhibition of flowering in short-day plants), etiolation (growth in darkness), cuticle coloration, anthocyanin synthesis (*e.g.,* in apples, red cabbage, and turnips), and several structural and physiological responses. P_{660} is capable of reversing many physiological reactions initiated by P_{730}. Even very brief exposures to light absorbed by P_{660} delays flowering in some short-day plants otherwise geared to flower by previous exposure to light of such wavelength that only the P_{730} phytochrome is involved. Much yet remains to be learned about the biochemistry of phytochromes and the reactions catalyzed or otherwise regulated by them.

Indole pigments. *Melanins.* These pigments produce buff, red-brown, brown, and black colours. Melanins occur widely in the feathers of birds; in hair, eyes, and skin of mammals, including humans; in skin or scales or both of many fishes, amphibians, and reptiles; in the ink of cephalopods (octopus, squid); and in various tissues of many invertebrates.

Melanins are polymers (compounds consisting of repeating units) of variable mass and complexity. They are synthesized from the amino acid tyrosine by progressive oxidation, a process catalyzed by the copper-containing enzyme tyrosinase. Extractable in very dilute alkali, melanins are also soluble when fresh and undried in very dilute acid solutions; they are bleached by hydrogen peroxide, which is sometimes applied to growing hair to create a blond effect, and by chlorine, chromate, and permanganate.

Composition of melanin

Pale-yellow, tawny, buff, reddish, brown, and black colours of hair and some feathers can arise from the presence of melanins in various phases of formation or subdivision in granules. The dark, light-absorbing sublayers of melanin that intensify reflected structural (Tyndall) blues or iridescent displays in feathers were mentioned above. Black melanins and brown melanoproteins occur in many invertebrate animals. Certain worms and many crustaceans and mollusks exhibit melanism in the skin.

The degree of natural melanization depends upon relative concentrations of copper and of the copper-containing enzyme tyrosinase. Dark hairs contain higher traces of copper than pale hairs do; should the intake of copper fall substantially below a fraction of a milligram per day, new fur emerges successively less dark. This trend is reversed by restoring sufficient copper to the diet.

All human skin except that of albinos contains greater or lesser amounts of melanin. In fair-skinned persons the epidermis, or outermost layer of the skin, contains little of the pigment; in the dark-skinned races epidermal deposits of melanin are heavy. On exposure to sunlight, human epidermis undergoes gradual tanning with increases in the melanin content, which helps to protect underlying tissues from injurious sun rays (see also INTEGUMENTARY SYSTEMS).

Tanning in man

Indigoids. Like melanins, the indigo compounds are excretory metabolic breakdown products in certain animals. But, in contrast to the melanins, their distribution as conspicuous pigmentary compounds is very limited, and they are not dark but red, green, blue, or purple.

One of the most common members of this group is indigo, or indigotin, which occurs as a glucoside (*i.e.,* chemically combined with glucose) in many plants of Asia, the East Indies, Africa, and South America. It has long been used as a blue dye.

Phenoxazones and sclerotins. Once confused with melanins, biochromes such as phenoxazones and sclerotins show a similar colour series (yellow, ruddy, brown, or black). Genetic research, notably with reference to eye pigments of the fruitfly, *Drosophila melanogaster,* has resulted in the description of a class of so-called ommochromes, which are phenoxazones. The ommochromes not only are conspicuous in the eyes of insects and crustaceans but have also been detected in the eggs of the echiurid worm *Urechis caupo* and in the changeable chromatophores in the skin of cephalopods. In addition to being responsible for the brown, vermilion, cinnabar, and other colours of insect eyes, ommochromes are also sometimes present in the molting fluid and integument. They are distinguished from the melanins by solubility in formic acid and in dilute mineral acids, by manifestation of violet colours in concentrated sulfuric acid, and by showing reversible colour changes with oxidizing and reducing agents. The ommochromes, which are derived from breakdown of the amino acid tryptophan, include ommatins and ommins. The ommatins, although complex in chemical structure, are relatively small molecules. The ommins are large molecules, in which the chromogenic moiety is seemingly condensed with longer chains, such as peptides (amino acids linked together).

Ommochromes in invertebrates

Sclerotins arise as a result of an enzyme-catalyzed tanning of protein. Certain roaches secrete a phenolase enzyme, the glucoside of a dihydroxyphenol, and a glycosidase. Mixing of these substances results in the release of the

phenolic compound from glucose and its combination, via a reaction catalyzed by the phenolase, with protein; the products are pink, ruddy, and ultimately dark-brown polymers that are incorporated into the insect's body cuticle and egg cases. Similar reactions take place in the carapace (the shell covering the body) of certain crustaceans.

Purines and pterins. Although the purine compounds cannot be classed as true pigments—they characteristically occur as white crystals—they often contribute to the general colour patterns in lower vertebrates and invertebrates. That purines are excretory materials is illustrated by the uric acid (or urates) and guanine found in the excrement of birds and of uric acid found in that of reptiles. Uric acid has also been detected in the mucus excreted by sea anemones, and urates are present in small amounts in the urine of higher apes and humans.

Manifestation of uric acid

The white, silvery, or iridescent chromatophores, both stationary iridocytes and changeable leucophores, of some fishes, amphibians, lizards, and cephalopods contain microcrystalline aggregates of the purine guanine; a layer of white skin on the underside of many fishes, called the stratum arginatum, is particularly rich in guanine.

Closely related to the purines and formerly classed among them are the pterins, so named from their notable appearance in and first chemical isolation from the wings of certain butterflies. Both purines and pterins contain a six-atom pyrimidine ring; in purines this ring is chemically condensed with an imidazole ring; pterins contain the pyrazine ring. Pterins occur as white, yellow, orange, or red granules in association with insect wing material.

Flavins (lyochromes). Flavins constitute a class of pale-yellow, greenly fluorescent, water-soluble biochromes widely distributed in small quantities in plant and animal tissues. The most prevalent member of the class is riboflavin (vitamin B_2).

Flavins are synthesized by bacteria, yeasts, and green plants; riboflavin is not manufactured by animals, which therefore are dependent upon plant sources. Riboflavin is a component of an enzyme capable of combining with molecular oxygen; the product, which is yellow, releases the oxygen in the cell with simultaneous loss of colour.

Metabolic role of riboflavin

Miscellaneous pigments. The chemical constitution of many pigments remains imperfectly known. Only a few of the more conspicuous examples are mentioned below.

Hemocyanins. Copper-containing proteins called hemocyanins occur notably in the blood of larger crustaceans and of gastropod and cephalopod mollusks. Hemocyanins are colourless in the reduced, or deoxygenated, state and blue when exposed to air or to oxygen dissolved in the blood. Hemocyanins serve as respiratory pigments in many animals, although it has not been established that they perform this function wherever they occur.

Hemerythrins. Iron-containing, proteinaceous pigments, hemerythrins are present in the blood of certain bottom-dwelling marine worms (notably burrowing sipunculids) and of the brachiopod *Lingula;* the pigments serve as oxygen-carriers.

Hemovanadin. Pale-green pigment, hemovanadin, is found within the blood cells (vanadocytes) of sea squirts (Tunicata) belonging to the families Ascidiidae and Perophoridae. The biochemical function of hemovanadin, a strong reducing agent, is unknown.

The vanadium-containing pigment of tunicates

Actiniochrome. A relatively rare pigment, actiniochrome occurs in red or violet tentacle tips and in the stomodeum (oral region) of various sea anemones. The pigment plays no recognized physiological role.

Adenochrome. Adenochrome is a nonproteinaceous pigment that occurs as garnet-red inclusions at high concentrations in the glandular, branchial heart tissues of *Octopus bimaculatus.* The compound contains small amounts of ferric iron and some nitrogen and gives a positive reaction for pyrroles. It is believed to be an excretory product.

(D.L.F./E.H.B.)

Control of coloration

GENETIC CONTROL

Coloration is in large measure determined genetically. As mentioned earlier, the inheritance of colour in garden peas provided part of the basis for the pioneering studies of heredity by Mendel. These studies led Mendel to postulate the existence of discrete units of heredity that segregate independently of one another during the formation of reproductive cells. The studies also led to his discovery of the phenomenon of dominance. The basic units of heredity are now known as genes, and the variant forms of a given gene are termed alleles. Among species that reproduce sexually, an individual normally possesses a pair of alleles for any gene—one inherited from the female parent and one from the male parent. These two alleles are situated at corresponding loci on the paired chromosomes found in diploid cells—*i.e.,* cells containing two similar sets of complementary chromosomes. Segregation of the alleles occurs during formation of reproductive cells, with the result that only one of the pairs enters each cell, which is called a haploid cell.

In his experiments Mendel crossed purple-flowered peas with white-flowered ones. The plants he used in these crosses were true-breeding for flower colour, meaning that the purple-flowered plants were descended for generations from only other purple-flowered plants, and that the white-flowered plants were likewise descended for generations from only other white-flowered plants. Because of these true-breeding characteristics, Mendel postulated that the original plants were homozygous for the trait of flower colour—in other words, that each plant carried a pair of identical heredity units (*i.e.,* alleles) for this trait. When he crossed purple-flowered peas with white-flowered ones, he obtained a first filial (F_1) generation in which all the offspring had purple flowers. He therefore deduced that the unit for purple (usually designated *R*) was dominant over the unit for white (*r*). Thus in the parental generation the purple-flowered plants can be designated *RR* (indicating that they are homozygous for the dominant allele), and the white-flowered plants can be symbolized as *rr*. The F_1 plants were heterozygous for flower colour (*Rr*), but they expressed purple colour because of the complete dominance of the allele *R* over *r*.

Inheritance of flower colour in peas

Dominance may be incomplete, however; a crossing between homozygous red Japanese four-o'clocks (*Mirabilis*) and homozygous white ones yields heterozygous *Rr* offspring, which are all pink. A cross of the heterozygous pink generation of four-o'clocks with each other yields a second generation with the colour ratio of 25 percent red (*RR*), 50 percent pink (*Rr*), and 25 percent white (*rr*). This is because each of the parent (F_1) plants produces equal numbers of *R*- and *r*-containing reproductive cells through segregation, and there is a random chance of either type of male haploid cell (gamete) fertilizing either of the two female types. For peas, on the other hand, the ratio resulting from a cross of parent (F_1) plants is three purple (one *RR* and two *Rr*) to one white (*rr*) because of the dominance of *R*.

Although the principle of inheritance of colour and coloration patterns in all organisms is like that for the two plants described above, it is usually far more complex. Within the species population, a particular gene may have multiple alleles instead of two; thus numerous combinations within any individual may be possible; in addition, the coloration may depend upon genes at several sites. In this case either all pairs may segregate simultaneously and more or less independently into the gametes, or the genes may be linked in their inheritance by location on the same chromosome. Such possibilities, together with different degrees of dominance, result in tremendously complex hereditary bases for the genetic control of colour and colour patterns within many species. For a fuller treatment of these principles, see GENETICS AND HEREDITY, THE PRINCIPLES OF: *Mendelian genetics.*

PHYSIOLOGICAL CONTROL

The development of coloration often depends upon regulatory substances (hormones) secreted by endocrine glands. In birds the level of the hormone thyroxine determines the coloration of feathers and bill, although specific seasonal biochromes are often laid down under the influence of sex hormones, as in the beak of the starling, which turns from black to yellow in early spring. The variability in

control among bird species is so great, however, that generalizations are impossible. Hormonally controlled colour changes also occur in mammals; for example, swellings in the genital areas that become pink due to vascularization during the reproductive season. The species specificity of coloration patterns, however, always depends on a genetically determined responsiveness of various target tissues to certain hormones.

Types of chromatophores

Chromatophores occur in cephalopods, crustaceans, insects, fishes, amphibians, and lizards and are responsible for the most rapid colour changes. They allow conspicuous display of a biochrome by dispersing it in the chromatophore-bearing surface, or they conceal the biochrome by concentrating it into small areas. Chromatophores are of three kinds. The chromatophoric organs of cephalopods consist of an elastic sac filled with biochrome and controlled by a ring of radiating muscle fibres. These fibres contract in response to neural stimulation, thereby stretching the sac into a broad, thin disk. Chromatophoric syncytia occur in crustaceans, the movement of biochrome being due to the ebb and flow of cytoplasm through fixed tubular spaces that collapse when the cell is contracted and fill when the cell expands. Chromatophoric syncytia are hormonally controlled. Cellular chromatophores, the third kind, are found in vertebrates. In these cells melanic granules flow in stable cellular processes that maintain a fixed position, unlike the contracting and expanding processes of the syncytia. Control among vertebrates is varied: chromatophores of bony fishes are controlled by the autonomic nervous system; those of elasmobranch fishes (sharks and rays) and lizards are controlled by hormones and nerves; those of amphibians are regulated by hormones alone.

One animal may contain biochromes of several colours, commonly red, yellow, black, and reflecting white; prawns also have a blue biochrome. By appropriate migrations of biochromes, an animal can achieve substantial alterations in colour or shade for varying periods of time. In prawns, dispersion of blue and yellow yields green; unequal dispersion of biochromes over parts of the body produces patterns of coloration.

Rapid physiological colour changes are supplemented by morphological ones, the animal either gradually synthesizing or destroying biochromes, usually in an adaptive manner (see the section *Coloration changes*).

(F.A.B./E.H.B.)

The adaptive value of biological coloration

Coloration and the pattern of coloration play a central role in the lives of plants and animals—even those species in which vision is lacking or not the dominant sense. For example, cryptic coloration often goes hand in hand with cryptic behaviour; nonreflective colours occur on the faces of birds that forage in bright sunlight; and abrasion-resistant coloration occurs more often among species that inhabit abrasive habitats than among species that inhabit nonabrasive habitats. The functions of biological coloration fall into three broad categories: (1) optical functions, in which coloration affects the animal's or plant's visibility to other animals; (2) visual functions, in which coloration affects the animal's own vision; and (3) physiological functions, in which the molecular properties of biochromes play a role unrelated to either optical signaling or vision.

OPTICAL FUNCTIONS: DECEPTIVE COLORATION

Deceptive coloration depends on four factors: the coloured organism, hereafter referred to as the organism; its model, which may be the background against which it is concealed; the spectral quality of the illumination; and the visual sensitivity and behaviour of the animal or animals that the organism is deceiving. To some extent the following discussion considers the relationships among the four factors separately; but in reality the deceptive, opitcal effect results from the interaction of all four factors. There are two basic types of deceptive coloration: (1) concealing coloration, or camouflage, in which the organism blends into its surroundings; and (2) mimicry, in which the organism is not hidden but rather presents a false identity by its resemblance to another species.

Camouflage. *Background matching.* Background matching is probably the most common form of concealment. It makes little difference whether the background model is an animate or inanimate object since both involve the initial establishment and continued maintenance of the concealment. Not only coloration but also the form and the activities or behaviour of the organism in relation to its model are important.

The simplest examples of background matching are provided by the fish eggs and planktonic (free-floating) larval fishes that exist in the uniformly blue environment of the open sea—*i.e.,* those that are pelagic. They usually possess minimal pigmentation and are transparent.

In other organisms and environments the behaviour and form of the organism become more important as adjuncts to coloration. Evidence of the importance of the choice of a proper background is provided by three differently coloured species of lizards of the genus *Anolis,* which form mixed hunting groups over the same background. Many of the individuals are easily perceived on this background, but, when disturbed, they conceal themselves by segregating according to species over the appropriately coloured backgrounds. Camouflage may also be accomplished through a change in coloration. Many flatfishes, for example, show a remarkable ability to match the pattern of the surface on which they are resting. Some nudibranchs, a group of marine gastropods, such as *Phestilla melanobrachia,* manage to establish and maintain their resemblance to the background by ingesting portions of their model, which is the living coral on which they live. The pigments in the coral polyps are deposited in diverticulae (branches) of the gut and occasionally in the epidermis and show through as nearly perfect camouflage. The slow-moving nudibranchs are very difficult to see on their coral host, and when they move to differently coloured coral, their coloration changes as their food source changes.

Alteration of coloration to match changing backgrounds

Some of the parasites that live on marine fishes conceal themselves in a similar manner. Flukes, or monogenean trematodes, gorge themselves on their hosts' tissues and biochromes and appear to remain within areas on the host that have similar pigmentation. The adaptive significance of the coloration is known to lie in escape from predation by the third party, cleaning organisms such as the fish *Labroides,* which feeds on the external parasites of other fishes. Several decorator crabs use portions of the model for concealment by picking up algae and sponges and placing them on the carapace (upper shell) to cover their own coloration; the algae and sponges continue to live as if in their normal habitat.

Disruptive coloration. Disruptive patterns, frequently a part of camouflage coloration, serve the function of visual disruption by forming a pattern that does not coincide with the contour and outline of the body. The blenny *Hypsoblennius sordidus,* for example, usually has a mottled coloration that crudely matches its background in terms of the size and colour of differently pigmented areas; it also has a series of darkly pigmented "saddles" that break up the outline contour of its back. This species also demonstrates the fact that the type of disruptive patterning may change when an individual shifts to another type of background. The saddled condition is found when the background is composed of disruptive elements of the same approximate size—*e.g.,* small sponges, barnacles, and patches of algae. But when the fish moves to an evenly coloured area, its coloration becomes stripes that run horizontally from head to tail.

Disruptive patterns are found in the coloration of many fish that form schools over the reef during daylight hours for protection against predation. When a predator approaches, the fishes form dense schools in which all of the individuals orient in the same direction. The movement of many individuals, coupled with their similar disruptive coloration, presents an extremely confusing spectacle, presumably one that makes it difficult for a predator to fix upon and attack any one.

Behaviour that aids the function of coloration

Some forms of disruptive coloration also function to conceal movement. Forward movement in concentrically

Flamingo *(Phoenicopterus ruber roseus)* showing carotenoid pigmentation in the plumage and leg skin.

Structural colour of the superb tanager *(Tangara fastuosa)* is tyndall blue.

Red colour in wing of white-crested turacos *(Tauraco leucolophus)* results from turacin, a pigment derived from porphyrin.

The silvery appearance of the butterfly fish *(Chaetodon)* is due to a deposit of guanine, a colourless purine.

Purple colour of sea urchin *(Strongylocentrotus purpuratus)* is attributable to the naphthoquinone compound, echinochrome.

Rivoli's hummingbird *(Eugenes fulgens)* has iridescent structural colour.

Pigmentation

banded snakes, for example, is difficult to perceive when the animal moves between reeds or long blades of grass.

Countershading. Another clue can lead to the recognition of an organism: its three-dimensional form, which causes the unilluminated portion of the body to be in shadow. Countershading is a form of coloration in which the upper surfaces of the body are more darkly pigmented than the unilluminated lower areas, giving the body a more uniform darkness and a lack of depth relief. Widespread among vertebrates, countershading is frequently superimposed over camouflage and disruptive colorations.

Countershading by luminescent organs

The light-producing organs, or photophores, of many deepwater fishes provide a unique form of countershading. Photophores occur in bands along the lower parts of the sides and are directed downward. Deepwater fishes live in the twilight zone of the sea, in which the illumination is too weak to allow little more than a silhouette of prospective prey sighted by a predator from below. The downward-projecting photophores may provide countershading by obliterating the silhouette when it is viewed by a predator from below.

The role of shape in relation to coloration. The shape of an organism is important in determining the total configuration for protection. Both concealment and mimicry may depend strongly on imitation of both the shape and coloration of the model. Deep-bodied schooling fishes frequently show vertical banding, and elongated forms usually bear horizontal stripes. This dichotomy may be partially related to different swimming patterns: deep-bodied fishes perform frequent lateral turns; elongated forms show frequent horizontal movement and change of position.

Mimicry. As mentioned above, deception may be accomplished by providing false information through mimicry. Aggressive mimicry occurs when a predator resembles its prey or a harmless third party. For example, the American zone-tailed hawk (*Buteo albonotatus*) is nearly black and has long narrow wings, and it glides in the company of similarly coloured and shaped vultures. The vultures do not prey on small animals and therefore do not cause fright reactions among them. The zone-tailed hawk exploits this lack of fear by suddenly diving on its prey from among the group of circling vultures.

Some organisms provide false information as to their identity by mimicking dangerous or inedible species. When a third party, such as a predator, fails to distinguish between the mimic and its inedible model, the relationship is termed Batesian mimicry (see MIMICRY). Batesian mimicry can be contrasted to those forms of camouflage in which organisms show an "imitative resemblance" to inanimate objects in their environment, such as the leaves or twigs of a tree. Imitative resemblance is a true concealing coloration in that it usually disguises the organism sufficiently so it is not perceived as distinct from its background. The form and coloration of a Batesian mimic, on the other hand, usually ensures that the organism will be perceived by animals, including predators, but that it will be identified with the harmful or distasteful model species. Batesian mimicry is thus both a deceptive and an advertising coloration, and it is effective only because the model species itself has a warning coloration (see below).

Batesian mimicry

OPTICAL FUNCTIONS: ADVERTISING COLORATION

Whereas concealing coloration reduces visual information, advertising coloration provides easily perceived information as to an organism's location, identity, and movement.

Attraction. The most commonly recognized forms of advertisement occur as intraspecific communication. Most important in such interactions are the organism, or signal sender, and the third party, or signal receiver; also important are illumination and the relationship between the organism and its background.

Reproductive signals. Courtship colorations function to attract and arouse a mate and to aid in the reproductive isolation of species. Although by no means universal, it is common, at least among vertebrates, to find that the male of the species has the brightest courtship colours. Bright colours are usually accompanied by movements and display postures that further enhance the display coloration. In some species a number of males form a communal display group in active competition for females. Examples among birds include manakins (Pipridae), cocks of the rock (*Rupicola*), and some grouse (Tetraonidae); similar communal displays occur in some giant species of fruit flies (*Drosophila*) found in the mountains of Hawaii. The male flies hold their variously adorned wings outstretched and perform a series of visual displays toward females.

Communal courtship systems

To be maximally efficient, courtship coloration should either be shown only by sexually ripe individuals or be unique to the individuals that are courting. In many birds this is accomplished by spreading coloured feathers that are otherwise largely concealed. In others, however, the coloration serves multiple functions or is present throughout the year, and courting individuals are rendered unique by other displays, perhaps of a visual or auditory nature. Many fishes show dramatic changes in coloration during courtship. In some species these changes are long-term, hormonally mediated alterations of coloration and frequently include a proliferation of the carotenoid (red and yellow) pigments. Other coloration changes in courting fishes are short-term alterations involving melanophores, which cause rapid colour changes. As a female approaches the male, his sexual arousal can be measured by the degree of coloration change. Luminescence is involved in courtship signals in a variety of animals; for example, different species of the common firefly (Lampyridae) show unique flashing codes.

Courtship flashing codes

Schooling signals. In gregarious animals, coloration, morphology, and general behaviour may identify an individual to others of its species and can aid in the formation of species aggregations throughout the year. This is seen in schooling fishes, in which the portion of the body moved by swimming motions frequently contrasts with the coloration of the rest of the body, apparently providing an attracting stimulus within the school.

Interspecific signals. Species that enter into symbiotic, or mutualistic, interactions may be brought together by advertising coloration. Many plants depend on insects and even certain birds and bats for pollination and the dispersal of seeds. The pollinator is attracted first to the flower of the plant from which it picks up pollen while feeding; then it visits another flower of the same species, transferring some of the pollen. The coloration and shape of the flowers attract the pollinators and provide information as to the species of the plant. The flowers of plants pollinated by insects usually have patterns of yellow, blue, and ultraviolet that evoke a strong response in the insect eye. They usually have a darkly coloured pattern near the centre of the flower, called the nectar guide, which orients the insect toward the proper pollinating location. Bees show a strong preference for flowers with intricate shapes and colorations. Intricate radial patterns seem to be the most attractive; in fact, bees cannot be trained to prefer a simple to an intricate pattern. Some orchids take advantage of the sexual behaviour of bees, the flowers being nearly perfect mimics of the female bees. A male bee attempting to copulate with the flower acquires the pollen capsules and transfers them to another flower (see MIMICRY).

The attraction of different species

Repulsion. *Territorial advertising.* During the reproductive season, many animals defend a particular area or territory that includes their nest or spawning site. Many other animals defend territories throughout the year. In either case, coloration is frequently important. In species in which the task of territorial defense is accomplished largely by one sex, strong sexual dimorphism usually exists, the more brightly coloured sex being the one that holds the territory. Both male- and female-territorial species are found within the diverse fish family Cichlidae. Species in which the male holds a territory are marked by large and colourful males, the females being smaller and camouflaged; in those species in which the female defends the territory the reverse is found. In still other species the fish pair and share the territory, and there is little sexual dimorphism.

Coloration frequently releases agonistic (flight or attack) behaviour in territorial animals and intimidates intruders. The flashing coloration displays of a dominant octopus are an excellent example of a visual battle in which the victor may be determined with little or no bodily contact.

Use of coloration to avoid fighting

Although similar advertising colorations may contribute to the spacing out of territorial animals, dissimilarity in coloration between members of a species may allow closer spacing. Many brightly coloured reef fishes, for example, defend territories or personal spaces. In many of these species the young and subadults, with radically different coloration from the adult, live within the territory of an adult but remain free from attack; after they assume adult coloration, however, they are driven away. The territories frequently function to ensure a food supply; because the juveniles utilize different food, they pose no threat to the adult's supply. As the juveniles age, their feeding habits overlap those of the adult, and spacing is necessary.

Warning, or aposematic, coloration. Certain advertising colorations warn a third party of dangerous or inedible qualities of the organism (aposematic colorations), such as spines, poisons, or other defensive weapons, allowing the possessor to avoid a potentially damaging interaction in which the weapon is used. Red, black, and yellow are common in this context and may represent aposematic colours recognized by many animals.

The advantage of warning

As discussed above, Batesian mimicry is the imitation of aposematic coloration by benign organisms, which thereby enjoy at least a portion of the protection of the model species. While Batesian mimicry involves deceptive coloration, resemblance in warning coloration need not provide false information. Müllerian mimicry refers to instances in which several noxious species display the same warning coloration, thus enabling potential predators to learn and generalize the signal easily. The black-and-yellow coloration of bees and wasps is a typical example.

OPTICAL FUNCTIONS: COMBINATION OF CONCEALING AND ADVERTISING COLORATION

Most animals need both concealment and advertisement. An animal may need to conceal itself from predators and to advertise its presence to symbionts or to members of its own species for reproductive purposes.

Many birds that conceal courtship coloration when their feathers are held close to the body present a brilliant display upon erecting their feathers. Similar mechanisms are common in many animals, such as *Anolis* lizards, which have brightly coloured throat fans that are visible only when erected during courtship or threat behaviour.

Substitution of coloured objects for bright plumage

Many bower birds (Ptilonorhynchidae) have bright courtship colorations, although some males of *Amblyornis* species do not. Instead, they decorate an elaborate bower with leaves, flower petals, and other brightly coloured objects, which attract females but provide no clue to predators as to the exact location of the male.

Some predators deceive with advertising coloration. The frogfishes, or shallow-water anglerfishes, are extremely difficult to detect against their background. They have intricate and obvious lures that are waved near the mouth on a long stalk; prey fishes attracted to the lure are eaten.

Coloration change is another obvious mechanism that can restrict advertisement to times when it is needed for purposes of communication. Many animals change from cryptic to noncryptic colorations as they change from their normal resting coloration to a display coloration during social interactions. These changes are particularly common in fishes and cephalopods, which have efficient neural mechanisms of coloration change.

OPTICAL FUNCTIONS: THE ROLES OF THE SELECTIVE AGENT AND OF ILLUMINATION

The selective agent. Of obvious importance in the evolution of coloration is the third party, which is the actual selective agent involved in the relationship between the organism and its background. Identification of the third party and the sensory and nervous system components used by it are important in order to understand thoroughly the adaptive nature of deceptive or advertising coloration.

In analyzing concealing coloration, the actual identification of the third party may have a profound influence on the interpretation of the coloration and behaviour. For example, the early stages of the green Scotch pine caterpillar (*Bupalus piniarius* and others) are found at the tips of pine needles, well camouflaged in this position. As they grow larger, they move into the bases of the needles and onto the branch. One explanation for the movement is that the older caterpillars are much larger than the background needle, thus rendering the camouflage less effective. Another factor appears to be a shift in the third party as the caterpillar ages; young caterpillars are preyed upon by spiders found on the twigs; larger caterpillars, by birds such as titmice (*Parus*).

Importance of the visual capabilities of the third party

After the initial identification of the third party, its visual capabilities must be investigated. The spectral sensitivity of its eyes must be determined, as must the way in which it perceives combinations of biochromes and their arrangements. The visual stimulus is subject to encoding and integrating steps as it passes from the eye to the cerebral cortex of the brain. Contrast and movement are amplified by some cells, while other properties, such as shape and intensity, are ignored. In humans, for example, contrast is greatly enhanced at the junction between a red and a blue stripe, producing the optical illusion that the two stripes never meet and are on different planes. Such phenomena may be of importance in disruptive coloration.

Advertisement is likewise subject to the visual capabilities of the third party, or signal receiver. Many species of plants have yellow flowers barely distinguishable to the human eye; when an ultraviolet camera is used to photograph such flowers, however, various bright patterns and nectar guides are revealed that appear to be highly species specific. The importance of strong contrast and contour in the attraction of insects to flowers is related to the perceptual qualities of the insect's compound eye, which shows maximal response to flickering stimuli and may depend upon similar qualities for much form discrimination.

In social signals, the visual system of a species is frequently maximally responsive to its own range of colorations. Butterflies of the genus *Dardanus,* for example, are maximally responsive to their own blue courtship coloration. The visual system and coloration are coadapted to provide an efficient signal mechanism. (G.S.Lo./E.H.B.)

Illumination. Most optical signals depend on sunlight reflected from the animal or plant. Therefore, the receiver's perception of the signal depends on the characteristics of the ambient illumination, which, in turn, depends on such variables as time of year, time of day, amount of cloud cover, amount of vegetation between the light source and the optical signal, and spectral reflectance of the habitat. Clear-sky sunlight with the Sun overhead is essentially white, but with the Sun low in the sky the light has a yellow or orange spectral emphasis. Light in broadleaf forests has a yellow-green emphasis, whereas light in conifer forests has a slight bluish emphasis. These small but consistent differences may affect the evolution of optical coloration.

VISUAL FUNCTIONS

Biological coloration can play a variety of roles in an animal's visual system. For example, facial coloration can help determine the amount of light that is reflected into the eyes. Among animals living in brightly lit habitats, too much reflected light could have undesirable effects on vision. It could, for example, produce blinding glare or dazzle; it might result in high luminance in parts of the visual field, thereby diminishing contrast in other parts of the field; or it could cause adaptation to a higher illuminance level than is appropriate for the remainder of the visual field. Birds that forage in sunlight for aerial insects—a visually demanding task—have bills that are black. Apparently the black coloration reduces reflectance that interferes with their vision.

The role of biochromes in vision

Vision itself depends on a biochrome that consists of a protein, opsin, attached to a chromophore. The chromophore may be either retinal (vitamin A_1), in which case the molecule is called rhodopsin; or 3-dehydroretinal (vitamin A_2), in which case the molecule is called porphyropsin. When light enters the eye and strikes the visual biochrome, the molecule undergoes a chemical change that stimulates the receptor nerve and thereby produces a visual stimulus.

In addition to the visual pigments, the eyes of many invertebrates contain biochromes that affect the spectrum of light that reaches the photoreceptors. Similarly, oil

droplets in the retina and epithelium of vertebrate eyes contain carotenoids that may affect colour perception. More importantly, the epithelium contains melanin, which absorbs stray light that penetrates the retina without being absorbed by the visual pigments. In insect eyes a similar function is performed by ommochromes in secondary pigment cells surrounding the photoreceptors.

Among many nocturnal vertebrates the white compound guanine is found in the epithelium or retina of the eye. This provides a mirrorlike surface, the tapetum lucidum, which reflects light outward and thereby allows a second chance for its absorption by visual pigments at very low light intensities. Tapeta lucida produce the familiar eyeshine of nocturnal animals.

PHYSIOLOGICAL FUNCTIONS

The discussion of biochromes earlier in this article touched upon the many important physiological roles of biological pigments, including that of the chlorophylls in photosynthesis and of the hemoglobins in oxygen transport. This section provides examples of other physiological effects of biological coloration.

Hair and feathers that contain melanin are more durable than those that lack this biochrome. Increased durability probably accounts for the dark, melanic wing tips of most birds. It may also be a contributing factor to the high proportion of black among birds that live in deserts, which are exceptionally abrasive habitats.

Absorption of solar energy

The absorption of solar energy by dark skin, scales, feathers, or hair is often associated with increased heat gain and reduced metabolic rates. Because birds lose a large amount of body heat through their uninsulated legs, dark leg coloration may help to warm the legs by absorbing solar energy, thereby reducing heat loss. Such reduced heat loss may explain why dark-legged North American woodwarblers (Parulidae) arrive in their northern breeding areas earlier than light-legged woodwarblers. Dark feathers, however, may actually reduce the amount of solar energy that penetrates to and is absorbed by a bird's skin. With fully erect plumage in moderate winds, a dark bird in full sunlight absorbs less heat into its body than a light bird does. This may also be a factor contributing to the high proportion of black among desert-dwelling birds.

Photoactivation of 7-dehydrocholesterol into vitamin D occurs throughout the epidermis of humans in the presence of ultraviolet light. The melanization of human skin may be an adaptation to optimize synthesis of vitamin D by permitting more or less ultraviolet radiation to penetrate the epidermis.

A widespread response to increased light levels is the addition of melanin, or darkening of the body—for example, tanning in humans. Such melanic shielding protects the tissues of the organism from potentially dangerous levels of ultraviolet radiation. Since the ultraviolet shield need protect only easily damaged cells in the nervous and reproductive systems, it does not necessarily have to lie in the skin but can instead be located internally, immediately around sensitive organs. When the ultraviolet shield is internal, external coloration may conform to other selection pressures.

Water is conserved by reducing evaporative loss and by reducing excretory water loss. Insects reduce evaporative water loss by adding melanin to the cuticle, melanin being more waterproof than other biochromes. The black-coloured beetle *Onymacris laeviceps* loses significantly less water than does the white-coloured beetle *O. brincki* when both species are kept without food under identical conditions. Quinones also darken insect exoskeletons, and in *Drosophila* quinones contribute to the low permeability of the exoskeleton. Some insects avoid excretory water loss by depositing nitrogenous wastes in the exoskeleton, which is shed periodically. In these species external coloration is a consequence of nitrogen excretion.

Some arthropods produce offensive odours as a means of defense against predators. These odours derive from *p*-benzoquinones in the exoskeleton and are correlated with the chromatic properties of the molecules. Consequently, coloration in these species may be a consequence of selection for chemical defense.

Coloration changes

COLORATION CHANGES IN INDIVIDUAL ORGANISMS

Short-term changes. Most rapid colour changes are chromatophoric ones that alter the colour of the organism through the dispersion or concentration of biochromes. Emotion plays a role in such changes among some cephalopods, fishes, and horned lizards (*Phrynosoma*). When excited, certain fishes and horned lizards undergo a transient blanching that probably results from the secretion of adrenaline (epinephrine), a hormone known to concentrate the dark biochrome of vertebrates. Excited cephalopods exhibit spectacular displays of colour, with waves of colour rippling across the body. Chromatophoric colour change is slower in vertebrates than in cephalopods. Although some fish may complete a colour change within a minute (compared to half a second or less for cephalopods), most vertebrates require several minutes to several hours.

Colour changes linked to external cycles

Colour changes extending over several hours are often entrained to external cycles. Fiddler crabs (*Uca*) that live in the intertidal zone show a complex pattern of cyclic chromatophoric colour change that is entrained not only to the local tidal cycle but also to the lunar and solar cycles. So important is this cyclic colour change that the response is innate to every part of the integument. The legs of a fiddler crab can be removed and sustained for a few days in saline solution; during this time melanophores in the legs continue to disperse and concentrate their melanin according to the cycle at the time they were removed from the body. (E.H.B.)

Changes in colour that extend over periods of several months may involve the synthesis or destruction of chromatophores or biochromes. The quantities of deposited guanine in some fishes vary in proportion to the relative lightness in colour of the background upon which they are living. Greenfish, or opaleye (*Girella nigricans*), kept in white-walled aquariums became very pale during a four-month period, storing about four times the quantity of integumentary guanine as was recoverable from the skins of individuals living in black-walled aquariums but receiving the same kind and amounts of food and the same overhead illumination. (D.L.F./E.H.B.)

Some chromatophores respond directly to relevant environmental stimuli, independent of the nervous system. Such response occurs in the young of some fish and of the clawed frog (*Xenopus*); but in older individuals the nervous system, which is by this time fully developed, controls responsiveness. More typically the chromatophore response is mediated by the sensorimotor system from the start. The eye plays a major role in cephalopods and most vertebrates, particularly in animals capable of matching complex backgrounds, but the pineal organ (a light-sensitive organ on top of the brain) and a generalized dermal light sense may also mediate the chromatophore response.

Seasonal changes. Seasonal changes of fields and forests include the annual colour changes involving foliage, flowers, fruits, and seeds of plants. Many birds and mammals undergo seasonal molts, replacing their plumage or pelage with differently coloured feathers or hair. Winter whitening

Winter whitening of the willow ptarmigan (*Lagopus lagopus*) and varying hare (*Lepus*) are examples of a shift in camouflage coincident with a change in the background coloration. Many songbirds adopt a bright, contrasting nuptial plumage during the breeding season, reverting to a drabber winter plumage during the postnuptial molt.

Seasonal colour changes are usually regulated by light (mediated by the visual or pineal systems) or by temperature. Decreasing day lengths initiate whitening in the willow ptarmigan, whereas falling temperatures initiate whitening in the weasel (*Mustela erminea*). The spring molt of the varying hare is stimulated by the lengthening day, but the rate of molt depends on temperature. Seasonal changes in coloration may occur without a molt as a result of bleaching or wear, for example, the bleaching of human hair in the summer sun and birds that have bright colours based on carotenoids.

Age-related changes. Colour changes during the life of an individual are common. Graying hair is a familiar

badge of the elderly, both in humans and, to varying degrees, in other mammals. Among primate groups, particularly gorillas and chimpanzees, silver hairs indicate both age and dominance. Young birds of many species have a juvenile plumage that gives way to either an adult plumage in short-lived birds or a series of immature plumages in longer-lived species. Most gulls, for example, are deep gray or brown during their first year and become increasingly white thereafter. Changes of colour are also associated with age and size in many fish; for example, the blue parrot fish changes from a vertically barred pattern to all blue in association with increasing age and size.

(F.A.B./E.H.B.)

COLORATION CHANGES IN POPULATIONS

Coloration changes occur not only in individuals but in populations as well. These latter result from evolutionary pressures—*i.e.*, agents of natural selection—that act upon the natural variations in colour types (morphs) found among the population. As a result of such pressures, certain colour morphs have increased odds of surviving and passing on their coloration pattern. Depending on the nature of the selection pressures, the population may come to include substantial numbers of individuals of different colour morphs; or one morph may become dominant, largely supplanting an earlier dominant colour form.

Polychromatism

When individual colour variation is discontinuous within a species, that species is said to be polychromatic. The white-throated sparrow (*Zonotrichia albicollis*) of North America, for example, has individuals with white-and-black head stripes and other individuals with tan-and-brown head stripes. The different colorations are not associated with age, sex, or geographic region. Polychromatism may evolve in response to predation. A predator that successfully takes one prey type may then concentrate its search on others of this type and hence may overlook differently coloured prey of the same species. The phenomenon—known as a perceptual set or a search image—is exemplified by the predator of the European snail *Cepaea*. Predators encounter one morph and form a search image; they continue to hunt for that one form until its increasing rarity causes the predator to hunt randomly, encounter a different morph, and form a new search image. In this way, oscillating selection pressures maintain several contemporaneous colour morphs among the snail population.

Evolutionary colour changes dictated by shifting selection are suggested by many populations that show geographical or temporal clines (graded series of morphological characters). For example, the common flicker (*Colaptes auratus*) has yellow markings in eastern North America and red markings in western North America, suggesting a change in selection pressure as one moves from east to west. The best documented temporal shift in selection is

Industrial melanism in moths

the industrial melanism of noctuid and geometrid moths in England and Europe. The proportion of melanic, or darkly coloured, individuals in about 70 species of moths has increased dramatically since the 1850s. This increase correlates with the Industrial Revolution and the associated pollution of the countryside. Prior to that time, tree trunks, the normal daytime resting place of these nocturnal moths, had been covered by scattered whitish lichens. The trunks have turned dark in areas of industrial development because the lichens have been killed by pollutants and the trunks have been dirtied by soot. Blotched gray moths, previously protected from predation by birds, are now vulnerable, while the dark moths are less conspicuous. The shift to melanic populations in the United States lagged behind that in England and Europe, as did the industrialization process; but in Michigan by the early 1970s darkly coloured individuals formed up to 97 percent of some populations in regions where melanism was unknown before 1927. Since the 1970s in England there has been a reversal in the number of melanic individuals of some species, a sign that efforts to curb air pollution are having far-reaching effects.

The many diverse functions discussed above lead to the inevitable conclusion that no single function can explain the coloration of living things. While biologists are far from a comprehensive theory that predicts the hues and patterns of coloration of plants and animals, such a theory will have to integrate the optical, visual, and physiological functions of biological coloration. (G.S.Lo./E.H.B.)

Colour

Vision is obviously involved in the perception of colour. A person can see in dim light, however, without being able to distinguish colours. Only when more light is present do colours appear. Light of some critical intensity, therefore, is also necessary for colour perception. Finally, the manner in which the brain responds to visual stimuli must also be considered. The colour green has a quite different meaning for a resident of a tropical rain forest than it has for a desert dweller. Even under identical conditions, the same object may appear red to one observer and orange to another. Clearly, the perception of colour depends on vision, light, and individual interpretation, and an understanding of colour involves physiology, physics, and psychology.

An object appears coloured because of the way it interacts with light. The analysis of this interaction and the factors that determine it are the concerns of the physics of colour. The physiology of colour involves the eye's and the brain's responses to light and the sensory data they produce. The psychology of colour is invoked when the mind processes the visual data, compares them to information stored in memory, and interprets them as colour.

This article concentrates on the physics of colour. For a discussion of colour as a quality of light, see the articles LIGHT and ELECTROMAGNETIC RADIATION. For the physiological aspects of colour vision, see the article SENSORY RECEPTION. See also the article PAINTING, THE ART OF for a discussion of the psychological and aesthetic uses of colour.

This article is divided into the following sections:

Colour and light

THE NATURE OF COLOUR

Aristotle viewed all colour to be the product of a mixture of white and black, and this was the prevailing belief until 1666, when Sir Isaac Newton's prism experiments provided the scientific basis for the understanding of colour. Newton showed that a prism could break up white light into a range of colours, which he called the spectrum (see Figure 1), and that the recombination of these spectral colours re-created the white light. Although he recognized that the spectrum was continuous, Newton used the seven colour names red, orange, yellow, green, blue, indigo, and violet for segments of the spectrum by analogy with the seven notes of the musical scale.

From K. Nassau, *Physics and Chemistry of Color* (1983); John Wiley & Sons, Inc.

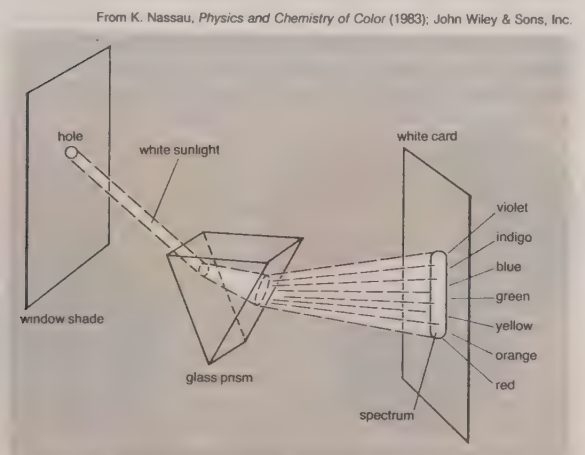

Figure 1: Newton's prism experiment of 1666.

Newton realized that colours other than those in the spectral sequence do exist, but noted that

> all the colours in the universe which are made by light, and depend not on the power of imagination, are either the colours of homogeneal lights [*i.e.,* spectral colours], or compounded of these.

Newton also recognized that

> rays, to speak properly, are not coloured. In them there is nothing else than a certain power . . . to stir up a sensation of this or that colour.

Nevertheless, terms such as "blue light" are commonly used and normally do not produce any confusion.

The unexpected difference between light perception and sound perception clarifies this curious aspect of colour. When beams of light of different colours, such as red and yellow, are projected together onto a white surface in equal amounts, the resulting perception of the eye signals a single colour (in this case, orange) to the brain, a signal that may be identical to that produced by a single beam of light. When, however, two musical tones are sounded simultaneously, the individual tones can still be easily discerned; the sound produced by a combination of tones is never identical to that of a single tone. A tone is the result of a specific sound wave, but a colour can be the result of a single light beam or a combination of any number of light beams.

Hue, saturation, and brightness

A colour can, however, be precisely specified by its hue, saturation, and brightness—three attributes sufficient to distinguish it from all other possible perceived colours. The hue is that aspect of colour usually associated with terms such as red, orange, yellow, and so forth. Saturation (also known as chroma, or tone) refers to relative purity. When

a pure, vivid, strong shade of red is mixed with a variable amount of white, weaker or paler reds are produced, each having the same hue but a different saturation. These paler colours are called unsaturated colours. Finally, light of any given combination of hue and saturation can have a variable brightness (also called intensity, or value), which depends on the total amount of light energy present.

THE VISIBLE SPECTRUM

Newton demonstrated that colour is a quality of light. To understand colour, therefore, it is necessary to know something about light. As a form of electromagnetic radiation, light has properties in common with both waves and particles. It can be thought of as a stream of minute energy packets radiated at varying frequencies in a wave motion. Any given beam of light has specific values of frequency, wavelength, and energy associated with it. Frequency, which is the number of waves passing a point in a unit of time, is commonly expressed in units of hertz (1 Hz = 1 cycle/second). Wavelength is the distance between corresponding points of two consecutive waves and is often expressed in units of nanometres (1 nm = 10^{-9} metres). The energy of a light beam can be compared to that possessed by a small particle moving at the velocity of light, except that no particle having a rest mass could move at such a velocity. The name photon, used for the smallest quantity of light of any given wavelength, is meant to encompass this duality, including both the wave and particle characteristics inherent in wave mechanics and quantum theory. The energy of a photon is often expressed in units of electron volts; it is directly proportional to frequency and inversely proportional to wavelength.

Light is not the only type of electromagnetic radiation—it is, in fact, only a small segment of the total electromagnetic spectrum—but it is the one form the eye can perceive. Wavelengths of light range from about 400 nm at the violet end of the spectrum to 700 nm at the red end (see the Table). (The limits of the visible spectrum are not sharply defined but vary among individuals; there is some extended visibility for high-intensity light.) At shorter wavelengths the electromagnetic spectrum extends to the ultraviolet region and continues through X rays, gamma rays, and cosmic rays. Just beyond the red end of the spectrum are the longer wave infrared rays (which can be felt as heat), microwaves, and radio waves. Radiation of a single frequency is called monochromatic. When this frequency falls in the range of the visible spectrum, the colour perception produced is that of a saturated hue.

The Range of the Visible Spectrum

colour*	wavelength (nm)	frequency (Hz × 10^{14})	energy (eV)
Red (limit)	700	4.29	1.77
Red	650	4.62	1.91
Orange	600	5.00	2.06
Yellow	580	5.16	2.14
Green	550	5.45	2.25
Cyan	500	5.99	2.48
Blue	450	6.66	2.75
Violet (limit)	400	7.50	3.10

*Typical values only.

THE LAWS OF COLOUR MIXTURE

Colours of the spectrum are called chromatic colours; there are also nonchromatic colours such as the browns, magentas, and pinks. The term achromatic colours is sometimes applied to the black-gray-white sequence. According to some estimates, the eye can distinguish some 10,000,000 colours, all of which derive from two types of light mixture: additive and subtractive. As the names imply, additive mixture involves the addition of spectral components and subtractive mixture concerns the subtraction or absorption of parts of the spectrum.

Additive colour mixture

Additive mixing occurs when beams of light are combined. The colour circle, first devised by Newton, is still widely used for purposes of colour design and is also useful when the qualitative behaviour of mixing beams of light is considered. Figure 2 shows a colour circle in which the spectral colours red, orange, yellow, green, cyan, indigo, and blue-violet are joined by the nonspectral colour magenta (a mixture of blue-violet and red light beams). White is at the centre and is produced by mixing light beams of approximately equal intensities of complementary colours (colours that are diametrically opposed on the colour circle), such as yellow and blue-violet, green and magenta, or cyan and red. Intermediate colours can be produced by mixing light beams, so mixing red and yellow gives orange, red and blue-violet gives magenta, and so on.

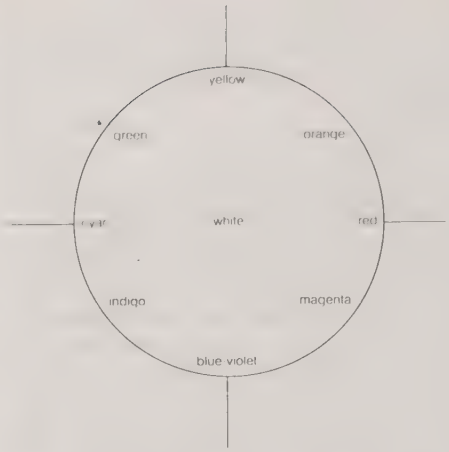

Figure 2: One form of Newton's colour circle.

The three additive primary colours are red, green, and blue; this means that by additively mixing the colours red, green, and blue in varying amounts almost all other colours can be produced, and when the three primaries are added together in equal amounts, white is produced.

Additive mixture can be demonstrated physically using three slide projectors fitted with filters so that one projector throws a beam of saturated red light onto a white screen, another a beam of saturated blue light, and the third a beam of saturated green light. Additive mixing occurs where the beams overlap (and thus are added together). Figure 3 (left) illustrates the results of such an experiment. As can be seen, where the red and green beams overlap, yellow is produced. If more red light is added or if the intensity of the green light is decreased, the light mixture becomes orange. Similarly, if there is more green light than red light, a yellow-green is produced.

Subtractive colour mixture

Subtractive colour mixing involves the absorption and selective transmission or reflection of light. It occurs when colorants (such as pigments or dyes) are mixed or when several coloured filters are inserted into a single beam of white light. For example, if a projector is fitted with a deep red filter, the filter transmits red light and absorbs other colours. If the projector is fitted with a strong green filter, red is absorbed and only green light is transmitted. If, therefore, the projector is fitted with both red and green filters, all colours are absorbed and no light is transmitted, resulting in black. Similarly, a yellow pigment absorbs blue and violet light while reflecting yellow, green, and red light (the green and red additively combining to produce more yellow). Blue pigment absorbs primarily yellow, orange, and red light. If the yellow and blue pigments are mixed,

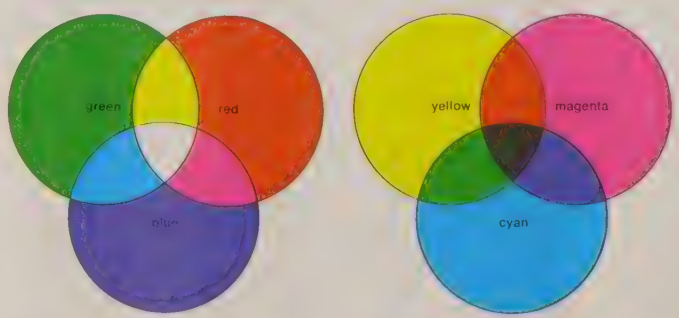

Figure 3: (Left) The additive mixing of red, green, and blue. (Right) The subtractive mixing of magenta, yellow, and cyan.

green is produced since it is the only spectral component that is not strongly absorbed by either pigment.

Because additive processes have the greatest gamut when the primaries are red, green, and blue, it is reasonable to expect that the greatest gamut in subtractive processes will be achieved when the primaries are, respectively, red-absorbing, green-absorbing, and blue-absorbing. The colour of an image that absorbs red light while transmitting all other radiations is blue-green, often called cyan. An image that absorbs only green light transmits both blue light and red light, and its colour is magenta. The blue-absorbing image transmits only green light and red light, and its colour is yellow. Hence, the subtractive primaries are cyan, magenta, and yellow (see Figure 3, right).

No concepts in the field of colour have traditionally been more confused than those just discussed. This confusion can be traced to two prevalent misnomers: the subtractive primary cyan, which is properly a blue-green, is commonly called blue; and the subtractive primary magenta is commonly called red. In these terms, the subtractive primaries become red, yellow, and blue; and those whose experience is confined for the most part to subtractive mixtures have good cause to wonder why the physicist insists on regarding red, green, and blue as the primary colours. The confusion is at once resolved when it is realized that red, green, and blue are selected as additive primaries because they provide the greatest colour gamut in mixtures. For the same reason, the subtractive primaries are, respectively, red-absorbing (cyan), green-absorbing (magenta), and blue-absorbing (yellow).

The measurement of colour

Colorimetry

The measurement of colour is known as colorimetry. A variety of instruments are used in this field. The most sophisticated, the spectrophotometers, analyze light in terms of the amount of energy present at each spectral wavelength. The emittance curves for the light sources shown in Figure 4 are typical spectrophotometer results, as is the reflectance curve of the paint pigment known as emerald green, shown in Figure 5.

It is difficult to describe the colour of a specific spectral energy distribution. Since the eye perceives only a single colour for any given energy distribution, it is necessary to express colour measurements in a perception-related way. Several systems exist and some are outlined below.

TRISTIMULUS MEASUREMENT AND CHROMATICITY DIAGRAMS

The tristimulus system is based on visually matching a colour under standardized conditions against the three primary colours, red, green, and blue; the three results are expressed as X, Y, and Z, respectively, and are called tristimulus values. The tristimulus values of the emerald-green pigment of Figure 5 are $X = 22.7$, $Y = 39.1$, and $Z = 31.0$. These values specify not only colour but also visually perceived reflectance, since they are calculated in such a way that the Y value equals a sample's reflectivity (39.1 percent in this example) when visually compared to a standard white surface by a standard (average) viewer under average daylight. The tristimulus values can also be used to determine the visually perceived dominant spectral wavelength (which is related to the hue) of a given sample; the dominant wavelength of the emerald-green pigment is 511.9 nm.

Such data can be graphically represented on a chromaticity diagram (see Figures 6 and 7). Standardized by the Commission Internationale d'Éclairage (CIE) in 1931, the chromaticity diagram is based on the values x, y, and z, where $x = X/(X + Y + Z)$, $y = Y/(X + Y + Z)$, and $z = Z/(X + Y + Z)$. Note that $x + y + z = 1$; thus if two values are known, the third can always be calculated and the z value is usually omitted. The x and y values together constitute the chromaticity of a sample. Light and dark colours that have the same chromaticity (and are therefore plotted at the same point on the two-dimensional chromaticity diagram) are distinguished by their different Y values (luminance or visually perceived brightness).

Luminance

When their x and y coefficients are plotted on a chromaticity diagram, the spectral colours from 400 nm to 700 nm follow a horseshoe-shaped curve; the nonspectral violet-red mixtures fall along the straight line joining the 400 nm point to the 700 nm point. All visible colours fall within the resulting closed curve, as shown in Figure 6. Points along the circumference correspond to saturated colours; pale unsaturated colours appear closer to the centre of the diagram. The achromatic point is the central point at $x = 1/3$, $y = 1/3$ (shown as W in Figure 7), where visually perceived white is located (as well as the pure grays and black, which vary only in the magnitude of the luminance Y).

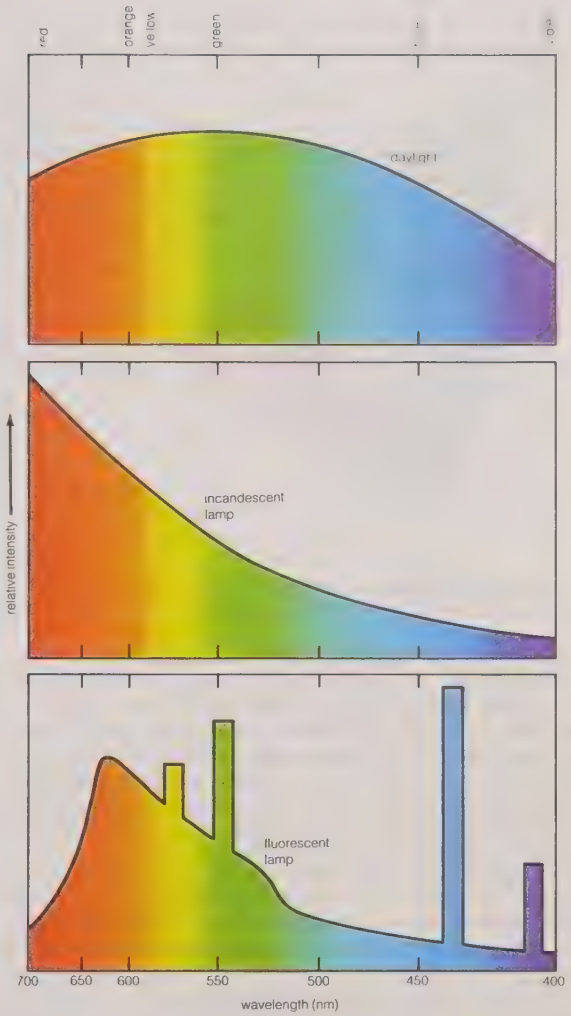

Figure 4: The energy distribution in light from daylight, an incandescent lamp, and a fluorescent lamp.

A straight line connecting any two points representing beams of light includes all the points representing colours formed by adding various amounts of the two beams. If the line passes through the achromatic point, the colours represented by its endpoints, when additively combined in the appropriate amounts, must form white; therefore all lines passing through the achromatic point terminate on the closed curve in saturated complementary colours.

Dominant wavelength and purity

By plotting the calculated $x = 0.245$ and $y = 0.421$ of the emerald-green pigment at point E on the chromaticity diagram in Figure 7 and extending a line through it from the achromatic point W to the saturated spectral boundary, it is possible to determine the dominant wavelength of the pigment colour, 511.9 nm. The colour of the pigment is the visual equivalent of adding white light and light of 511.9 nm in amounts proportional to the lengths n (the distance between points E and W) and m (the distance between E and the point of the dominant wavelength) in Figure 7. The purity equals $100n/(m + n)$ percent—in this case, 22.8 percent. A purity of 100 percent corresponds to a pure saturated spectral colour and 0 percent to the achromatic colours (white, gray, and black).

The colour of a specific red apple of $Y = 13.0$, $x = 0.460$, $y = 0.287$ has its x and y values plotted at R in Figure 7. The line from the achromatic point W intersects the chromaticity diagram boundary at a saturated nonspectral purple-red at P. The dominant colour designation is then obtained by extrapolating the line in the opposite direction to a saturated spectral colour and is given as "complementary dominant wavelength 495 nm" or 495c. The colour of this apple is therefore the visual equivalent of a mixture of white light and the 495c saturated purple-red in the intensity ratio of the distances p to q shown in Figure 7 with a purity of $100p/(p + q)$ percent.

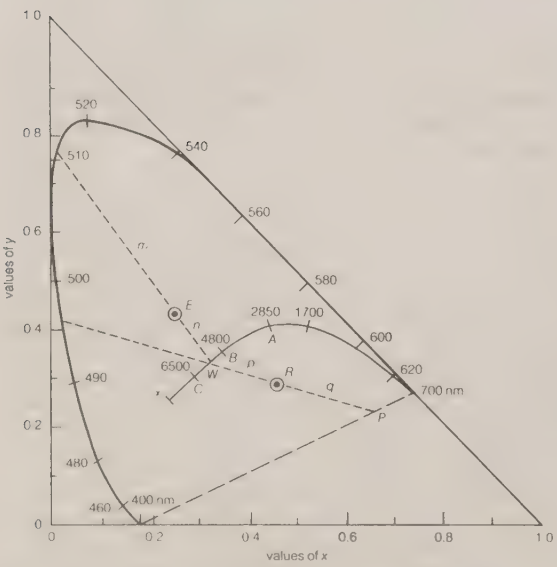

Figure 7: The location on the chromaticity diagram of the achromatic point *W*, the emerald-green pigment *E*, a red apple *R*, the incandescence curve with temperatures in kelvins, and the standard CIE illuminants *A*, *B*, and *C*.

Light from incandescent sources, further described below, falls on the solid curve marked with temperatures in this figure, following the sequence saturated red to saturated orange to unsaturated yellow to white to unsaturated bluish white for an infinite temperature indicated as ∞. The points *A*, *B*, and *C* on the curve are CIE standard illuminants that approximate, respectively, a 100-watt incandescent filament lamp at a colour temperature of about 2,850 K, noon sunlight (about 4,800 K), and average daylight (about 6,500 K).

COLOUR ATLASES

Munsell system

Calculating chromaticity and luminance is a scientific method of determining a colour, but for the rapid visual determination of the colour of objects, a colour atlas such as the *Munsell Book of Color* is often used. In this system colours are matched to printed colour chips from a three-dimensional colour solid whose parameters are hue, value (corresponding to reflectance), and chroma (corresponding to purity). These three parameters are illustrated schematically in Figure 8. The central vertical axis provides a 10-step value scale extending from black at the bottom to white at the top. There are 100 hues divided into 10 groups around the vertical axis; each group has a colour name and consists of 10 subdivisions assigned a number from 1 to 10. The chroma scale starts at 0 at the vertical axis and extends radially outward from 10 to 18 steps depending on hue and value. The red apple discussed earlier would be designated 10RP 4/10 in the Munsell system, indicating a specific reddish purple hue 10RP, a value of 4, and a chroma of 10. Interpolated values are used to give more precise designations, so the emerald-green pigment can be specified as 5.0G 6.7/11.2.

A system that is useful when such precision is not required is the ISCC–NBS (Inter-Society Color Council–National Bureau of Standards) Centroid Color Charts. It has 267 numbered colour designations and uses descriptive terms such as very pale purple, light yellowish brown, and grayish blue; the red apple is 258 (moderate purplish red) in this system, the emerald-green pigment is 139 (vivid green). Other colour atlases include the Ostwald colour system, based on mixtures of white, black, and a high chroma colour; the Maerz and Paul dictionary of colour; the Plochere colour system; and the Ridgway colour standards.

Physical and chemical causes of colour

According to the law of energy conservation, energy can be converted from one form to another, but it cannot be created or destroyed. Consequently, when a photon of light is absorbed by matter, usually by an atom, molecule, or ion, or a small grouping of such units, the photon disappears and its energy is gained by the matter. Similarly, when matter emits light, it loses the energy carried away by the photons. A given atom or molecule cannot emit light of any arbitrary energy, since quantum theory explains that only certain energy states are possible for a given system.

An example of permitted energy levels is shown at the left in Figure 9 for the trivalent chromium ion present in a crystal of aluminum oxide; this is the colorant that provides the red colour of the gemstone ruby. Present in this energy level scheme is the ground state, designated $^4A_2$; this is the energy state of the chromium ion in ruby when in the dark. When illuminated by white light, either a photon of energy 2.2 eV or a photon of energy 3.0 eV can be absorbed, raising the system to the $^4T_2$ or $^4T_1$

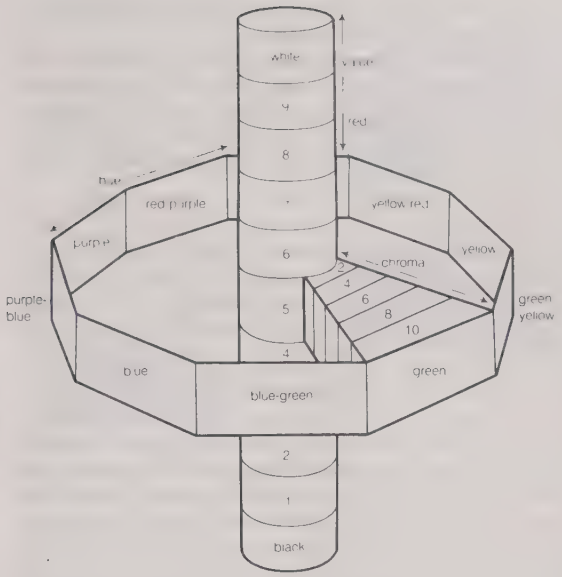

Figure 8: The hue, value, and chroma coordinates of Munsell's colour solid.

energy levels, respectively (in this system light cannot be absorbed into the level ^2E because of certain quantum limitations designated selection rules). These two energy transitions, broadened by the thermal atomic vibrations at room temperature into absorption bands, correspond to absorption of the violet and green-yellow parts of white light passing through the ruby, as shown at the centre in Figure 9. The remaining transmitted light consists of the strong red and weak blue parts of the spectrum, resulting in the deep red ruby colour with a slight purple overtone.

Energy transitions and the corresponding absorption of light

The chromium ion in ruby now contains excess energy, but the selection rules permit return to the ground state only through the intermediate ^2E energy level as shown at left in Figure 9. Part of the absorbed energy appears as a slight warming of the ruby. The other part is emitted as a photon producing a bright red fluorescence (best seen when the ruby is illuminated with ultraviolet radiation in the dark). The ruby has now returned to the ground state and energy has been conserved. This is just one explanation of the occurrence of colour. Although all occurrences or causes of colour involve the excitation of electrons, to simplify explanation, this article classifies the physical and chemical causes of colour into 15 groups. The first three involve transitions among the energy levels of excitations, vibrations, and rotations as explained by quantum theory. The next four involve modifications of this approach covered by the ligand field and molecular orbital theories. The following four involve the energy band formalism of solid state physics, and the final four are explained by geometrical and physical optics theory.

SIMPLE EXCITATIONS, VIBRATIONS, AND ROTATIONS

Incandescence. Incandescent light is produced when hot matter releases parts of its thermal vibration energy as photons. At medium temperatures, say 800° C, the object's radiation energy reaches a peak in the infrared, with only a small intensity at the red end of the visible spectrum. As the temperature is raised, the peak moves toward and finally into the visible region. At successively higher temperatures the object becomes "red-hot," then orange, yellow, and finally "white-hot"; the very hottest of stars have a bluish-white colour. This sequence of colours is known as the blackbody radiation sequence and is included in the chromaticity diagram of Figure 7. Examples of incandescence include daylight (see Figure 4), candlelight, and light from tungsten filament lamps (see Figure 4), flashbulbs, the carbon arc, and pyrotechnic devices such as flares and fireworks.

Blackbody radiation sequence

Gas excitation. Gas excitation involves the emission of light by a chemical element present as a gas or vapour. When a gas such as neon or a vapour such as sodium or mercury is excited electrically, the electrical energy raises the atoms into high energy states from which they decay back to ground state with the emission of photons. This leads to the red light seen in neon tubes and the yellow and blue light seen in sodium and mercury vapour lamps, respectively. The same yellow sodium light is emitted when sodium atoms are thermally excited by being heated in a gas flame. In addition to being produced electrically or by chemical reactions, gas excitations can also result from interaction with energetic particles, as in auroras, where energetic particles emitted in solar storms excite gases high in the Earth's atmosphere to produce various colour effects.

Vibrations and rotations. All molecules have some vibration or rotation energy as a result of chemical bonding, but the energy involved is too low to interact directly with visible light. The frequency of vibration can be increased, however, by strengthening the chemical bonding involving very light atoms. For example, the bond between hydrogen and oxygen is stronger in liquid water and solid ice than in an isolated H_2O molecule. The corresponding increase in vibration frequencies allows some absorption at the red end of the spectrum and produces the pale blue colour characteristic of pure water and ice when seen in bulk. Similar vibrations as well as rotations contribute to the purple colour of iodine, the brown of bromine, and the blue-to-green colours seen in the oxygen-rich gas flame of a kitchen range.

LIGAND FIELDS

Transition metal impurities. Most chemical compounds are colourless when pure; examples include sodium chloride (ordinary table salt), aluminum oxide, naphthalene (moth flakes), and diamond. In these compounds all electrons are present in pairs. Such paired electrons are particularly stable and need very high energies to become unpaired and form excited energy levels. Only ultraviolet light is energetic enough to be absorbed, which explains the absence of visible light absorptions and the absence of colour. The compounds of a number of metals, most commonly iron, chromium, nickel, cobalt, and manganese, do, however, produce coloured salts. These metals are the transition elements, which contain unpaired electrons in their compounds. Excited energy levels are readily formed by these unpaired electrons, resulting in the absorption of photons and the production of colour.

Aluminum oxide, Al_2O_3, also known as corundum or colourless sapphire when pure, can serve as an example. In this compound each trivalent aluminum ion is surrounded by six oxygens in the configuration of a slightly irregular octahedron. The electric field at the aluminum site of this octahedral arrangement of oxygens is known as the ligand field (an older term, implying a simpler approach, was crystal field). If aluminum oxide contains chromium as an impurity, so that one out of every 100 aluminums is replaced by a chromium, which has unpaired electrons, then the ligand field produces a change in the energy levels

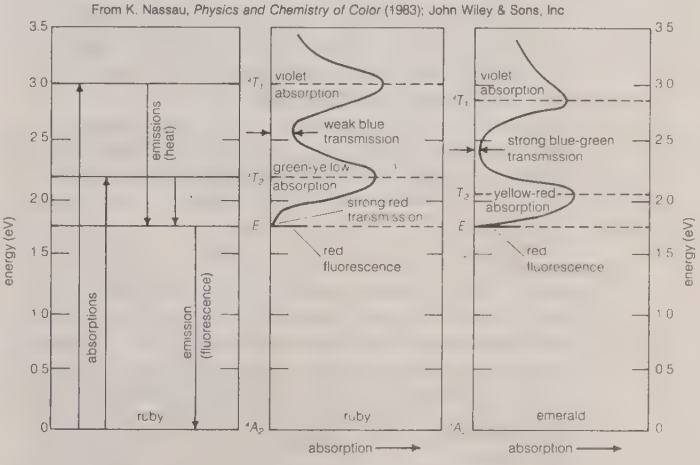

Figure 9: (Left) The energy level diagram of ruby with allowed transitions and (centre) the resulting absorption and fluorescence spectra. (Right) The absorption and fluorescence spectra of emerald.

that an isolated chromium ion would have. This gives the specific energy level scheme shown at the left in Figure 9, which leads to the light absorption curve at the centre of the Figure and produces the red colour (as well as the red fluorescence) of the chromium-containing aluminum oxide, also known as the gemstone ruby, as described above.

If chromium similarly replaces 1 or 2 percent of the aluminum in the compound beryllium aluminum silicate, a combination also known as the gemstone emerald, then the ligand field has the same geometry but is somewhat weaker, a result of the effect of the berylliums and silicons on the strength of aluminum-oxygen bonding. This produces small shifts in some of the absorption energy levels compared to ruby and results in the absorption spectrum shown at the right in Figure 9. These shifts have resulted in the almost total elimination of the red transmission and an intensification of the blue-green transmission, leading to an emerald-green colour. The ^2E energy level of Figure 9 has not shifted; accordingly, red ruby and green emerald show the same red fluorescence.

Other such transition metal impurities cause the colours of red iron ore and the gemstones yellow citrine and blue-to-green aquamarine (all coloured by a small percentage of iron impurity).

Transition metal compounds. The transition metal may be present not as an impurity but as an essential part of the substance. An example is chromium oxide, Cr_2O_3, also known as the pigment chrome green, in which the relatively weak ligand field of the chromium-oxygen bonding at the chromiums produces colour in a similar manner to that in the emerald discussed above. Additional examples are the copper-containing blue-to-green gem materials malachite, azurite, and turquoise, as well as the patina on copper statues, the red iron ore hematite, and the cobalt-glass pigment smalt.

MOLECULAR ORBITALS

Organic compounds. All dyes and most pigments, whether natural or synthetic, are complex organic compounds whose molecular structures include a "colour-bearing" group known as a chromophore, usually a short conjugated system (a chain of atoms connected by alternating single and double bonds). The bonding electrons holding the molecule together can be viewed as belonging to the whole molecule. Simple conjugated chains have electronic transitions that absorb radiation only in the ultraviolet range of the spectrum. If, however, the chain is long, the resulting transitions between molecular orbital energy levels require less energy, and absorption shifts to longer wavelengths. The carotenes are naturally occurring examples of extended conjugated systems; they absorb some light in the violet or blue range of the spectrum and therefore appear yellow or orange in colour. The same effect occurs if the number of electrons present on a conjugated chain is modified by the addition of groups of atoms known as auxochromes. Auxochromes can be either electron acceptors or electron donors. Nitrophenylenediamine compounds contain both types of auxochromes. They absorb in the blue part of the spectrum and are often used in hair dyes because the small size of the molecules allows them to penetrate into hair easily.

Organic dyes occur widely in the plant and animal kingdoms as well as in the modern synthetic dye and pigment industry. Just as with ligand-field energy levels, some of the absorbed energy may be re-emitted in the form of fluorescence.

Charge transfer. Aluminum oxide containing a few hundredths of 1 percent of titanium is colourless. If it contains a similar amount of iron, a very pale yellow colour may be seen. If both impurities are present together, the aluminum oxide has a magnificent deep blue colour and is known as the gemstone sapphire. The colour is the result of charge transfer, in which the absorption of light energy allows an electron to move from one ion to another, resulting in a temporary change in the valence state of both ions:

$$Fe^{2+} + Ti^{4+} \longrightarrow Fe^{3+} + Ti^{3+}.$$

This process requires energy; since the energy corresponds to an absorption in the yellow region of the spectrum, the complementary colour blue results.

Other forms of charge transfer lead to the black of the iron oxide magnetite; the brilliant blue colour of potassium ferric ferrocyanide, the pigment Prussian blue; the yellow-to-orange chromates and dichromates; and the deep blue gemstone lapis lazuli, which has the same composition as the pigment ultramarine.

ENERGY BANDS

Metals. The valence electrons, which in other substances produce bonding between individual atoms or small groups of atoms, are shared equally by all the atoms in a piece of a metal. These delocalized electrons are thus able to move over the whole piece of metal and provide the metallic lustre and good electrical and thermal conductivities of metals and alloys. Band theory explains that in such a system individual energy levels, as at the left in Figure 9, are replaced by a continuous region called a band, as in the density of states diagram for copper metal shown in Figure 10. This diagram shows that the number of electrons that can be accommodated in the band at any given energy varies; in copper the number declines as the band approaches being filled with electrons. The number of electrons in the copper fill the band to the level shown, leaving some empty space at higher energies.

Band theory

When a photon of light is absorbed by an electron near the top of the energy band, the electron is raised to a higher available energy level within the band as shown by the arrow in Figure 10. The light is so intensely absorbed that it can penetrate to a depth of only a few hundred atoms, typically less than a single wavelength. Because the metal is a conductor of electricity, this absorbed light, which is, after all, an electromagnetic wave, induces alternating electrical currents on the metal surface. These currents immediately re-emit the photon out of the metal, thus providing the strong reflection of a polished metal surface.

The efficiency of this process depends on certain selection rules. If the efficiency of absorption and re-emission is approximately equal at all optical energies, then the different colours in white light will be reflected equally well, leading to the "silvery" colour of polished silver and iron surfaces. In copper the efficiency of reflection decreases with increasing energy; the reduced reflectivity at the blue end of the spectrum results in a reddish colour. Similar considerations explain the yellow colour of gold and brass.

Pure semiconductors. In a number of substances a band gap appears in the density of states diagram (see Figure 11). This can happen, for example, when there are an average of exactly four valence electrons per atom in a pure substance, resulting in a completely full lower band, called the valence band, and an exactly empty upper band, the conduction band. Because there are no electron energy levels in the gap between the two bands, the lowest

Band-gap energy

energy light that can be absorbed corresponds to arrow *A* in Figure 11; this represents the excitation of an electron from the top of the valence band up to the bottom of the conduction band and corresponds to the band-gap energy designated E_g. Light of any higher energy can also be absorbed as indicated by the arrows *B* and *C*.

If the substance represented by this Figure has a large band gap, such as the 5.4 eV of diamond, then no light in the visible spectrum can be absorbed and the substance appears colourless when pure. Such large band-gap semiconductors are excellent insulators and are more usually treated as ionic or covalently bonded materials.

The pigment cadmium yellow (cadmium sulfide, also known as the mineral greenockite) has a smaller band gap of 2.6 eV, which permits absorption of violet and some blue but none of the other colours. This leads to its yellow colour as can be deduced from the colour scale at the right in Figure 11. A somewhat smaller band gap that permits absorption of violet, blue, and green produces the colour orange; a yet smaller band gap as in the 2.0 eV of the pigment vermillion (mercuric sulfide, the mineral cinnabar) results in all energies but the red being absorbed, which leads to a red colour. All light is absorbed when the band-gap energy is less than the 1.77 eV (700 nm) limit of the visible spectrum; narrow band-gap semiconductors, such as the lead sulfide galena, therefore absorb all light and are black. This sequence of colourless, yellow, orange, red, and black is the precise range of colours available in pure semiconductors.

Doped semiconductors. If an impurity atom, often called a dopant, is present in a semiconductor (which is then designated as doped) and has a different number of valence electrons from the atom it replaces, extra energy levels can be formed within the band gap. If the impurity has more electrons, such as a nitrogen impurity (five valence electrons) in a diamond crystal (consisting of carbons, each having four valence electrons), a donor level is formed. Electrons from this level can be excited into the conduction band by the absorption of photons; this occurs only at the blue end of the spectrum in nitrogen-doped diamond, resulting in a complementary yellow colour. If the impurity has fewer electrons than the atom it replaces, such as a boron impurity (three valence electrons) in diamond, a hole level is formed. Photons can now be absorbed with the excitation of an electron from the valence band into the hole level. In boron-doped diamond this occurs only at the yellow end of the spectrum, resulting in a deep blue colour as in the famous Hope diamond.

Fluorescent lamps

Some materials containing both donors and acceptors can absorb ultraviolet or electrical energy to produce visible light. For example, phosphor powders, such as zinc sulfide containing copper and other impurities, are used as a coating in fluorescent lamps to convert the plentiful ultraviolet energy produced by the mercury arc into fluorescent light (see Figure 4). Phosphors are also used to coat the inside of a television screen, where they are activated by a stream of electrons (cathode rays) in cathodoluminescence, and in luminous paints, where they are activated by white light or by ultraviolet radiation, which causes them to display a slow luminous decay known as phosphorescence. Electroluminescence results from electrical excitation, as when a phosphor powder is deposited onto a metallic plate and covered with a transparent conducting electrode to produce lighting panels.

Injection electroluminescence occurs when a crystal contains a junction between differently doped semiconducting regions. An electric current will produce transitions between electrons and holes in the junction region, releasing energy that can appear as near-monochromatic light, as in the light-emitting diodes (LEDs) widely used on display devices in electronic equipment. With a suitable geometry, the emitted light can also be monochromatic and coherent as in semiconductor lasers.

Colour centres. A colour centre often involves a solid that is missing an atom, such as sodium chloride, an ionic crystal that consists of a three-dimensional array of positively charged sodium ions and negatively charged chloride ions. When a negative chloride ion is missing from the crystal, a way electrical neutrality can be maintained is if a free electron occupies the spot vacated by the chloride ion, forming an F-centre (after the German *Farbe,* "colour"). This replacement electron can be viewed as providing a trapping energy level within the large band gap.

F-centres

Some form of relatively high energy, such as ultraviolet radiation or high-energy X rays or gamma rays, can then be used to promote an electron from the valence band into the trap, which contains excited energy levels such as that designated E_a in Figure 12. The E_a level for the sodium chloride F-centre occurs at 2.7 eV and can absorb blue light, leading to a yellow-brown colour; such a defect is called a colour centre. The electron in this excited energy level is still within the trap. Only by supplying energy corresponding to E_b can the electron leave the trap and return via the conduction band directly to the valence band. This can happen if the crystal is heated, resulting in bleaching of the colour centre. If E_b is about the same size as E_a, bleaching can occur merely while the material is being illuminated, leading to optical bleaching. If E_b is sufficiently small, the material may even fade in the dark at room temperature. This occurs in self-darkening sunglasses: the ultraviolet energy present in sunlight produces darkening, and room temperature leads to fading as soon as ultraviolet light is no longer present.

GEOMETRICAL AND PHYSICAL OPTICS

Dispersion and polarization. In his 1666 experiment, shown in Figure 1, Newton discovered what is now called

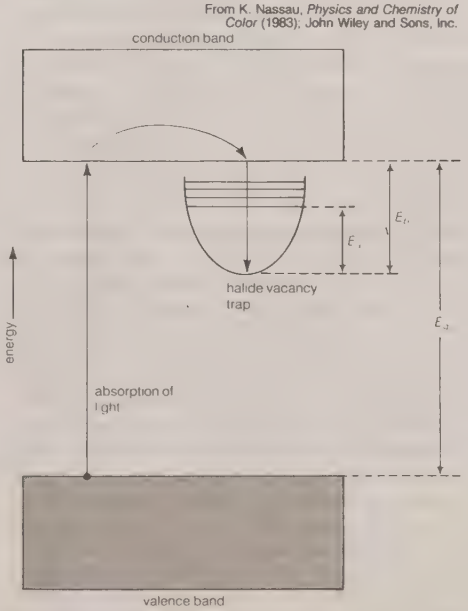

Figure 12: Chloride vacancy trap in the band gap of salt and its filling by the absorption of energy.

dispersion or dispersive refraction. He showed that a light beam is bent, or refracted, as it passes from one medium to another—*e.g.*, from air into glass. The natures of the two media as well as the wavelength of the light involved determine the degree of refraction, with shorter wavelengths bending more than longer wavelengths. Dispersion in a faceted diamond produces coloured flashes of light, in drops of water in the atmosphere it produces primary and secondary rainbows, and in ice crystals in thin clouds it produces a variety of halos and arcs around the Sun and Moon.

Absorption related to dispersion

Dispersion has its origin in absorption. Even a colourless, transparent substance, such as glass, absorbs electromagnetic radiation in the ultraviolet (derived from the unpairing of paired electrons and their further excitation) and in the infrared (from the vibrations of atoms, molecules, and larger structural units). It is a combination of these two effects that produces dispersion: only a vacuum has no absorptions and therefore no dispersion.

A rope can be snapped so that a wave movement travels from one end to the other; the motion of the wave can be from side to side, up and down, or in any direction perpendicular to the rope. Similarly, an unpolarized light wave travels in a single direction but vibrates in random directions perpendicular to its travel. When a light wave vibrates in only one direction, it is called polarized.

Light can be polarized in passing through certain substances (such as a crystal of calcium carbonate, the mineral calcite, or a sheet of polarizing film) that block out all waves except those vibrating in a particular direction. Polarized white light can interact with various doubly refracting materials (ones in which the index of refraction varies according to the direction in which the light waves passing through it vibrate) to produce colour. This technique is often used to view rocks or structural models; the colours produced are then studied to determine mineral composition or to analyze stress.

Scattering. When light strikes fine particles or an irregular surface, it is deflected in all directions and is said to be scattered. When the scattering particles are very small compared to the wavelength of light, the intensity of the scattered light is related to that of the incident light by the inverse fourth power of the wavelength (Rayleigh scattering). As a result, light at the blue end of the spectrum is scattered much more intensely than that at the red end.

Rayleigh scattering

The light from the Sun is scattered by dust particles and clusters of gas molecules, and the scattered blue rays seen against the dark background of outer space cause the sky to appear blue. At sunrise and sunset, when sunlight travels the farthest, almost all of the blue rays are scattered and the light that reaches the Earth directly is seen as predominantly red or orange. Scattering also causes that epitome of rare occurrences, the blue Moon (seen when forest fires produce clouds composed of small droplets of organic compounds). Most blue and green bird feathers involve scattering, as do many animal and some vegetable blues. Scattering also produces the blue colour of eyes, particularly the intense blue eyes of most infants, whose yellow-to-dark-brown pigments such as melanin have not yet all been formed so that only blue is seen against the dark interior of the eye.

If the size of the scattering particles approaches the wavelength of light or exceeds it, the complex Mie scattering theory applies and explains colours other than blue; white is scattered at the largest sizes, as in fog and clouds.

Interference. Two light waves of the same wavelength can interact under appropriate circumstances so as to reinforce each other if they are in phase or to cancel each other if they are out of phase. If a beam of light falls on a thin film, such as an oil slick on a puddle of water, part of the beam is reflected from the front of the oil film and part from the back. Depending on the thickness of the film, the two reflected beams can reinforce or cancel.

When monochromatic light falls on a film of tapering thickness, a series of dark and light bands, known as interference fringes, is produced. With white light the sequence of overlapping light and dark bands from the spectral colours leads to Newton's colours. The film appears black or gray where it is thinnest and the light waves cancel; as it becomes progressively thicker, it appears white, then yellow, orange, red, violet, blue, green, yellow, orange-red, violet, and so on. Newton's colours can also be seen in cracks in glass or in crystals, in a soap bubble, and in antireflection coatings such as on camera lenses.

Newton's colours

A large number of structural colorations in biologic systems also derive from thin film interference. These structures usually feature multiple layers and are frequently backed by a dark layer of melanin, which intensifies the colour by absorbing the nonreflected light. Such colorations are usually iridescent; the colours appear metallic and change with orientation. Examples include pearl and mother-of-pearl, the transparent wings of houseflies and dragonflies, the scales on beetles and butterflies, and the feathers of hummingbirds and peacocks. The eyes of many nocturnal animals contain multilayer structures that improve night vision and can produce iridescent reflections in the dark.

Diffraction. Interference is also involved in diffraction, another phenomenon that produces colour. Diffraction is the term used to describe the spreading of light at the edges of an obstacle and the subsequent interference that occurs. When a monochromatic beam of light falls on a single edge, a sequence of light and dark bands is produced; and with white light a sequence of colours much like the Newton colour sequence appears.

A diffraction grating consists of a regular two- or three-dimensional array of objects or openings that scatter light according to its wavelength over a wide range of angles. As these deflected waves interact, they reinforce one another in some directions to produce intense spectral colours. This effect can be seen by looking at a distant streetlight or flashlight through a black cloth umbrella. Diffraction arrays that reveal spectral colours in direct sunlight exist on the wings of some beetles and the skins of some snakes. Perhaps the most outstanding natural diffraction grating, however, is the gemstone opal. Electron microscope photographs reveal that an opal has a regular three-dimensional array of equal-size spheres, about 250 nm (0.00001 inch) in diameter, which produce the diffraction.

The perception of colour

COLOUR EFFECTS

When a person views an opaque coloured object, it is only the light deflected from the object that can activate the visual process in the eye and brain. Because different illuminants have different spectral energy distributions, as shown in Figure 4, a given object in these illuminations will reflect different energy distributions. Yet the eye and brain are such superb systems that they are able to compensate for such differences, and normal-appearing colours are perceived, a phenomenon called colour constancy.

Colour constancy

Colour constancy does not apply, however, when there are subtle differences in colour. If, for example, two orange objects, one coloured by an orange pigment, the other by a combination of red and yellow pigments, match precisely in daylight, in the light of a tungsten lamp one may appear more reddish than the other. Because of this effect, called metamerism, it is always necessary to follow precisely the illumination and viewing conditions specified when comparing a sample colour to one in a colour atlas.

The intensity of illumination also affects colour perception. At very low light levels, blue and green objects appear brighter than red ones compared to their relative brightness in stronger illumination, an effect known as the Purkinje shift. At higher levels of illumination, there is a related shift in hues, called the Bezold-Brücke effect, such that most colours appear less red or green and more blue or yellow as the intensity of illumination increases.

If a bright spot of white light is projected onto a screen uniformly illuminated with a pale blue light, the effect known as simultaneous colour contrast makes the white light appear pale yellow and the blue light seem grayer than if the two were viewed separately. The complementary hue is induced by the adjacent illumination. Successive colour contrast, which occurs when a person stares at one colour and then shifts to another, produces the same effect. A person who stares at a pattern of colours for some

time and then looks at a white area sees a negative afterimage of the pattern in complementary hues. This effect, also called chromatic adaptation, is what causes browns to appear reddish to someone who has just viewed a green lawn. Thus, even when the colour of a given object is measured and its physical cause identified, visual effects can prevent the precise perception of that colour from being specified. Some of these effects can be explained fairly simply by changes in the sensitivity of the eye's receptors to different colours as intensity changes, by fatigue in specific receptors, or by receptor inhibition; others are not understood. In fact, scientists did not know the process by which the eye and brain perceive colour until the early 1960s and even now do not understand all the details.

COLOUR VISION

The trichromatic theory

One of the most successful theories of colour vision, the trichromatic theory, was first proposed around 1801 by Thomas Young, an English physician, and refined about 50 years later by the German scientist Hermann von Helmholtz. Based on experiments in colour matching, this theory postulates three types of colour receptors in the eye. The actual existence of such receptor cells, known as cones (from their shapes), was finally confirmed in the early 1960s. The three types of cones have maximum sensitivities in the blue, green, and red regions of the spectrum, with absorption peaks near 445 nm, 535 nm, and 565 nm, respectively. These three sets are often designated as S, M, and L for their sensitivity to short, medium, and long wavelengths. The trichromatic theory explains that colour vision results from the relative intensity of response of the S, M, and L cones. (Equal stimulation of all three gives the perception of white.) There is obviously a close connection between this trichromatic theory and the tristimulus value system.

One of the trichromatic theory's strengths is that the existence of several kinds of colour blindness can be simply explained as the lack of function of one or more sets of the cones. If one set of cones does not function, dichromatism results. People with deuteranopia (M set missing) or protanopia (L set missing) perceive only blue and yellow. In the much rarer tritanopia the S cones are missing and only green and red are perceived. Persons who have no functioning cone system suffer from the extremely rare monochromatism and can perceive only grays.

The opponent process theory

Although the trichromatic theory seems to explain much about colour vision, other theories have also been supported and studied, especially the opponent process theory. First proposed by the German physiologist Ewald Hering in 1878, this approach presumes that colour vision involves three mechanisms, each responding to a pair of opposites, namely, light–dark, red–green, and blue–yellow. It is based on many psychophysical observations, including the fact that blue and yellow (and also red and green) cannot coexist in any perceived colour; there are no bluish yellows (or reddish greens). Several of the contrast and afterimage effects can be explained very simply by this approach.

It is now recognized that the trichromatic and opponent process theories are not incompatible. They have been combined in a number of zone theories, which postulate that the cones function in a trichromatic manner in one zone, while in another zone the signals from the cones are combined in neural cells so as to produce one achromatic (white–black) and two chromatic (blue–yellow and green–red) signals, which are then interpreted in the brain. Although it is clear that zone theories, encompassing both trichromatic and opponent colour theories, are fully successful in explaining the many aspects of colour perception, there are still details that remain to be worked out.

The psychology of colour

The most important aspect of colour in daily life is probably the one that is least defined and most variable. It involves aesthetic and psychological responses to colour and influences art, fashion, commerce, and even physical and emotional sensations. One example of the link between colour and emotion is the common perception that red, orange, yellow, and brown hues are "warm," while the blues, greens, and grays are "cold." The red, orange, and yellow hues are said to induce excitement, cheerfulness, stimulation, and aggression; the blues and greens security, calm, and peace; and the browns, grays, and blacks sadness, depression, and melancholy. It must be remembered, however, that the psychological perception of colour is subjective, and only general comments about its features and uses can be made.

Colours are not universal. Some languages do not contain separate words for green and blue or for yellow and orange, while Eskimos use 17 words for white as applied to different snow conditions. When colour terminology in different cultures is compared, certain patterns are observed consistently. All languages have designations for black and white. If a third hue is distinguished, it is red; next comes yellow or green, and then both yellow and green. Blue is the sixth colour named, and brown is the seventh. Finally, in no particular sequence, the colours gray, orange, pink, and purple are designated.

The role of cultural conditioning

Like colour terminology, colour harmony, colour preferences, colour symbolism, and other psychological aspects of colour are culturally conditioned, and they vary considerably with both place and historical period. One cross-cultural study showed that American and Japanese concepts of warm and cold colours are essentially the same, but that in Japan blue and green hues are perceived to be "good" and the red-purple range as "bad," while in the United States the red-yellow-green range is considered "good" and oranges and red-purples "bad." The colour of mourning is black in the West, yet other cultures use white, purple, or gold for this purpose. Many languages contain expressions that use colour metaphorically (common examples in English include "green with envy," "feeling blue," "seeing red," "purple passion," "white lie," and "black rage") and therefore cannot always be translated literally into other languages because the colour may lose its associated symbolic meaning.

Colour symbolism serves important roles in art, religion, politics, and ceremonials, as well as in everyday life. Its strong emotional connotations can affect colour perception so that, for example, an apple- or heart-shaped figure cut from orange paper may seem to have a redder hue than a geometric figure cut from the same paper because of the specific psychological meaning that is associated with the shape.

In addition to emotional associations, factors that affect colour perception include the observer's age, mood, and mental health. People who share distinct personal traits often share colour perceptions and preferences. For example, schizophrenics have been reported to have abnormal colour perception, and very young children learning to distinguish colours usually show a preference for red or orange. Many psychologists believe that analyzing an individual's uses of and responses to colour can reveal information about the individual's physiological and psychological condition. It has even been suggested that specific colours can have a therapeutic effect on physical and mental disabilities.

Physical and emotional reactions to colour

Although these medical benefits are still in question, colour has been shown to cause definite physical and emotional reactions in humans and in some animals. Rooms and objects that are white or in light shades of "cool" colours may appear to be larger than those that are in intense dark or "warm" colours; black or very dark colours have a slimming, or shrinking, effect, as is well known to designers and decorators. A "cool" room decorated in a pale blue requires a higher thermostat setting than a "warm" room painted a pale orange in order to achieve the same sensation of warmth. People who view a display of unusual colours produced by special illumination may experience headaches and nervous disorders; tasty wholesome food served under such conditions appears repulsive and may even induce illness. Some colours induce a feeling of pleasure in the observer. When an affectively positive, or pleasurably perceived, colour is viewed after a less pleasant colour, it produces more pleasure than when viewed by itself, an effect known as affective contrast enhancement.

The effect of combinations of colours on an observer depends not only on the individual effects of the colours but also on the harmony of the colours combined and the composition of the pattern. Artists and designers have been studying the effects of colours for centuries and have developed a multitude of theories on the uses of colour. The number and variety of these theories demonstrates that no universally accepted rules apply; the perception of colour depends on individual experience.

Columbus

Christopher Columbus, Master Mariner and Navigator, was born in Genoa, Italy, probably between August 26 and October 31, 1451, and died at Valladolid, Spain, May 20, 1506. He was the eldest son of Domenico Colombo, a Genoese wool worker and small-time merchant, and Susanna Fontanarossa, his wife. Columbus made four transatlantic voyages that opened the way for European exploration, exploitation, and colonization of the Americas. He has long been called the "discoverer" of the New World, although Vikings such as Lief Eriksson had visited North America five centuries earlier.

Columbus sailed under the sponsorship of Ferdinand and Isabella, the Catholic Monarchs of Aragon, Castile, and Leon in Spain. On the first and second voyages (Aug. 3, 1492–March 15, 1493, and Sept. 25, 1493–June 11, 1496) Columbus sighted the majority of the islands of the Caribbean and established a base in Hispaniola (now divided into Haiti and the Dominican Republic). On the third voyage (May 30, 1498–October 1500) he reached Trinidad and Venezuela and the Orinoco River delta. On the fourth (May 9, 1502–Nov. 7, 1504) he explored the coasts of Jamaica, Honduras, Nicaragua, Costa Rica, and the Panamanian region of Veragua (Veraguas). Although at first full of hope and ambition, an ambition partly gratified by his title "Admiral of the Ocean Sea," awarded to him in April 1492, and by the grants enrolled in the Book of Privileges (a record of his titles and claims), Columbus died a disappointed man. He was removed from the governorship of Hispaniola in 1499, his chief patron, Queen Isabella, died in 1504, and his efforts to recover his governorship of the "Indies" from King Ferdinand were, in the end, unavailing. In 1542, however, the bones of Columbus were taken from Spain to the Cathedral of Santo Domingo in what is now the Dominican Republic, where they may still lie.

Advances in Columbus scholarship

The period between the quatercentenary celebrations of Columbus' achievements in 1892–93 and the quincentenary ones of 1992 saw great advances in Columbus scholarship. A huge number of books about Columbus appeared in the 1990s, and the insights of archaeologists and anthropologists now complement those of sailors and historians. This effort has given rise, as might be expected, to considerable debate. The past few years have also seen a major shift in approach and interpretation; the older pro-European and imperialist understanding has given way to one shaped from the perspective of the inhabitants of the Americas themselves. According to the older understanding, the "discovery" of the Americas was a great triumph, one in which Columbus played the part of hero in accomplishing the four voyages, in being the means of bringing great material profit to Spain and to other European countries, and in opening up the Americas to European settlement. The second perspective, however, has concentrated on the destructive side of the European intrusions, emphasizing, for example, the disastrous impact of the slave trade and the ravages of imported disease on the indigenous peoples of the Caribbean region and the American continents. The sense of triumph has diminished accordingly, and the view of Columbus as hero has now been replaced, for many, by one of a man deeply flawed. While Columbus' abilities as a navigator are rarely doubted in this second perception, and his sincerity as a man sometimes allowed, he is emphatically removed by it from his position of honour. The further interventions of political activists of all kinds have hardly fostered the reconciliation of these so disparate views.

Columbus, oil painting by Sebastiano del Piombo, 1519. In the Metropolitan Museum of Art, New York.

In an attempt at a balanced account, attention will first of all be restored to the nature and quantity of the surviving written and material sources about Columbus. All informed scholarly comment must depend primarily upon these. Then the admiral's achievements and failures will be examined in light of recent research. Finally, the focus will briefly return to the debate, which is far from ended.

MAJOR WRITTEN SOURCES

The majority of the surviving primary sources for Columbus were written to be read by other people. There is, then, an element of manipulation about them. This fact needs to be borne fully in mind for their proper understanding. Foremost among these sources are the journals written by Columbus himself for his sovereigns—one for the first voyage, now lost but able partly to be reconstructed; one for the second, almost wholly gone; and one for the third, again accessible through reconstructions made by using later quotations, like the first. Each of the journals may be supplemented by letters and reports to and from the sovereigns and their trusted officials and friends, provisioning decrees from the sovereigns, and, in the case of the second voyage, letters and reports of letters from fellow voyagers (especially Michele da Cuneo, Diego Alvarez Chanca, and Guillermo Coma). There is no journal and only one letter from the fourth voyage, but a complete roster and payroll survive from this, alone of all the voyages, and Columbus' younger son Ferdinand (b. *c.* 1488) traveled with the admiral and left an eyewitness account. The so-called Pleitos de Colón, judicial documents put forward by the Pinzón family in 1515 against the claims of Columbus' heirs, throw oblique further light upon the explorations. Ferdinand Columbus' *The Life of the Admiral Christopher Columbus,* the *Historia de los Reyes Católicos* (*c.* 1500) of Andrés Bernáldez (a friend of Columbus' and chaplain to the archbishop of Seville), and the *Historia de las Indias* put together about 1550–63 by Bartolomé de las Casas (bishop of Chiapas and champion of the indigenous people of the Americas) supplement the other narratives.

Columbus' library

Further important material may be gleaned from the few books still extant from the admiral's own library. Some of these were extensively annotated, often by the admiral and sometimes by his brother Bartholomew. The readings and annotations from Columbus' copies of the *Imago mundi* by the 15th-century French theologian Pierre d'Ailly (a compendium containing a great number of cosmological and theological texts), the *Historia rerum ubique gestarum* of Pope Pius II, published in 1477, the version of *The Travels of Marco Polo* known as the *De consuetudinibus et*

condicionibus orientalium regionum of Francesco Pipino (1483–85), Alfonso de Palencia's late 15th-century Castilian translation of Plutarch's *Parallel Lives*, and the 15th-century humanist Cristoforo Landino's Italian translation of the *Natural History* of Pliny the Elder cast a most important light on Columbus' intentions and presuppositions. So do the contents of certain other books known to have been in his possession, such as the *Guide to Geography* of the Greek astronomer and geographer Ptolemy, the *Catholicon* of the 15th-century encyclopedist John of Genoa, and a popular handbook to confession, the mid-15th-century *Confessionale* produced by the Dominican St. Antoninus of Florence. The whole shows that the admiral was adept in Latin, Castilian, and Italian, if not expert in all three. He annotated primarily in Latin and Spanish, very rarely in Italian. He had probably already read and annotated at least the first three named texts before he set out on his first voyage to the "Indies." His Christian interests are manifest. He was plainly a deeply religious and reflective man as well as a distinguished seaman, and, being largely self-taught, had a reverence for learning, especially, perhaps, the learning of his most influential Spanish supporters. The Book of Prophecies, a collection of prophetic passages and pronouncements, taken largely from the Bible and seeming to bear upon his western voyages, which seems largely to have been put together between September 1501 and March 1502 (with additions until *c.* 1505) by Columbus and his friend the Carthusian friar Gaspar Gorricio, is a striking manifestation of these sensibilities and seems to contain many passages and extracts that were personally important to the admiral.

Direct material remains of Columbus' travels are few. Efforts to find the Spaniards' first settlement on Hispaniola (Haiti), at Navidad, have so far failed, but the local chieftain's settlement nearby has been identified, and the present-day fishing village of Bord de Mer de Limonade may be close to the original site. Concepción de la Vega, which Columbus also founded on Hispaniola, on the second voyage, may be the present La Vega Vieja, in the Dominican Republic. Remains at the site of La Isabela are still to be fully excavated as are those at Sevilla la Nueva, on Jamaica, where Columbus' two caravels were beached on the fourth voyage. The techniques of skeletal paleopathology and paleodemography are being applied with some success to determine the fates of the native populations.

LIFE

Early career and the first voyage. Little is known of Columbus' early life. His career as a seaman began effectively in the Portuguese marine. After surviving a shipwreck off Cape St. Vincent at the southwestern point of Portugal in 1476, he based himself in Lisbon, together with his brother Bartholomew. Both were employed as chartmakers, but Columbus was principally a seagoing entrepreneur. In 1477 he sailed to Iceland and Ireland with the marine, and in 1478 he was buying sugar in Madeira as an agent for the Genoese firm of Centurioni. In 1479 he met and married Felipa Perestrello e Moniz, a member of an impoverished noble Portuguese family. Their son, Diego, was born in 1480. Between 1482 and 1485 Columbus traded along the Guinea coast and made at least one voyage to the Portuguese fortress of São Jorge da Mina on the Gold Coast of equatorial West Africa, gaining knowledge of Portuguese navigation and the Atlantic wind systems along the way. His search for support for an Atlantic crossing in both Portugal and Spain has encouraged conspiracy theorists to suspect a secret pact with King John II of Portugal, but there is no evidence of this. Felipa died in 1485, and Columbus took as his mistress Beatriz Enríquez de Harana of Córdoba, by whom he had his second son, Ferdinand. By 1486 Columbus was firmly in Spain, asking King Ferdinand and Queen Isabella for patronage. After at least two rejections, he at last obtained royal support in January 1492. This was achieved chiefly through the interventions of the Spanish treasurer, Luis de Santángel, and of the Franciscan friars of La Rábida, near Huelva, with whom Columbus had stayed in the summer of 1491. Juan Pérez of La Rábida had been one of the queen's confessors and perhaps procured him the crucial audience. Royal patronage was finally advanced in the euphoria that followed the fall of Granada, the last stronghold of the Moors in Spain, on Jan. 2, 1492.

Royal patronage

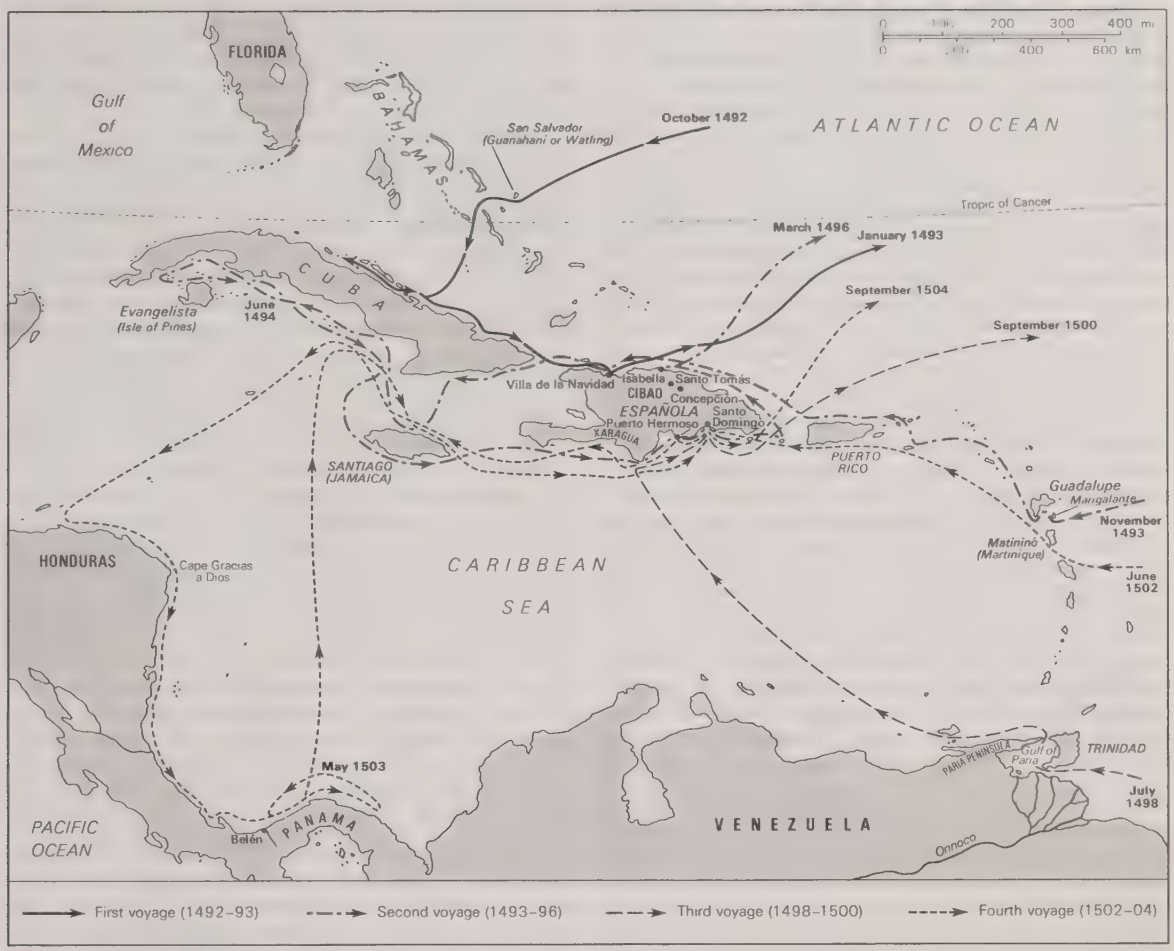
Columbus had been present at the siege of Granada in January 1492. He was in fact riding back from it to La Rábida when he was recalled to court and the vital royal audience. Granada's fall encouraged Spanish Christians to believe that they might indeed triumph over Islām, albeit chiefly, perhaps, by the back way round the globe. In the letter that prefaces his journal of the first voyage, the admiral vividly evokes his own hopes and binds them all together with the conquest of the infidel, the victory of Christianity, and the westward route to discovery and Christian alliance:

> ... and I saw the Moorish king come out of the gates of the city and kiss the royal hands of Your Highnesses ... and Your Highnesses, as Catholic Christians ... took thought to send me, Christopher Columbus, to the said parts of India, to see those princes and peoples and lands ... and the manner which should be used to bring about their conversion to our holy faith, and ordained that I should not go by land to the eastward, by which way it was the custom to go, but by way of the west, by which down to this day we do not know certainly that anyone has passed; therefore, having driven out all the Jews from your realms and lordships in the same month of January, Your Highnesses commanded me that, with a sufficient fleet, I should go to the said parts of India, and for this accorded me great rewards and ennobled me so that from that time henceforth I might style myself "Don" and be high admiral of the Ocean Sea and perpetual Governor of the islands and continent which I should discover ... and that my eldest son should succeed to the same position, and so on from generation to generation.

Thus a great number of interests were involved in this great project, which was, in essence, the attempt to find a route to the rich continent of Cathay (or modern China), to India, and to the fabled gold and spice islands of the East by sailing westward over what was presumed to be open sea. Columbus himself clearly hoped to rise from his humble beginnings in this way, to accumulate riches for his family, and to join the ranks of the nobility of Spain. In a similar manner, but at a more exalted level, the Catholic Monarchs sought, through such an enterprise, to gain greater status among the monarchies of Europe, especially against their main rival, Portugal. Then, in alliance with the papacy (in this case, with the Borgia pope Alexander VI [1492–1503]), they might hope to take the lead in the Christian defense against the infidel. The power of the Ottomans and other Islāmic nations of the eastern Mediterranean was growing at an alarming pace, threatening the Christian monarchies themselves. This power had also effectively closed the land routes to the East, via the Caspian Sea, Samarkand, and northern India, and made the sea route south from the Red Sea extremely hard to access.

At a more elevated level still, Franciscan preachers sought to prepare for the end of the world, as they interpreted the Book of Revelation to prophesy. According to the eschatological vision contained in Revelation, Jerusalem would be recaptured by Christendom and a Christian emperor installed in the Holy Land. These events were a precondition for the coming, and defeat, of Antichrist and the conversion of the whole human race and, ultimately, for the Last Judgment. The westward project would, it was hoped, help to finance a crusade to the East. It might also be another arm of it, linking with Christians such as Prester John, a legendary Christian ruler of the East, and his descendants, who, it was thought by many, still survived east of the lands of the infidel. The Great Khan of the Golden Horde was himself held to be interested in Christianity. Columbus carefully carried a letter of friendship from his sovereigns to the Great Khan with him on his journeys. Finally, the Portuguese explorer Bartolomeu Dias was known to have pressed southward along the coast of West Africa, beyond São Jorge da Mina, in an effort to find an easterly route to Cathay and India by sea. It would never do to allow the Portuguese to find the sea route first.

Christian missionary fervour, the power of Castile and



The voyages of Christopher Columbus.

Aragon, the fear of Portugal, the lust for gold, the desire for adventure, the hope of conquests, and Europe's genuine need for a reliable supply of herbs and spices for cooking, preserving, and medicine all combined to produce that explosion of energy which launched the first voyage. Adventurous emigration may have been encouraged by the decree signed March 31, 1492, ordering the expulsion of the Jews from Spain.

Columbus' miscalculations

The time has come to lay to rest, finally and for good, the ghost of the notion that Columbus had ever thought that the world was flat. Europeans had known that the Earth was spherical in shape ever since the spread of the popular *Etymologies* of St. Isidore of Seville, produced (in Spain) in the early 7th century. Columbus' miscalculations, such as they were, lay in quite other areas. First, his estimate of the sea distance to be crossed to Cathay was wildly inaccurate. A chart (now lost) supplied by the Florentine mathematician and geographer Paolo Toscanelli, together with Columbus' preference for the calculations of the ancient Greek geographer Marinus of Tyre, encouraged him to reject Ptolemy's estimate of the journey from West to East overland and to substitute a far longer one. Again, on the authority, primarily, of the 13th–14th-century Venetian Marco Polo's *Travels,* he conceived the idea that the lands of the East stretched out far around the back of the globe, with the island of Cipango, or Japan, located a further 1,500 miles from the mainland of Cathay and itself surrounded by islands. This cluster of islands might, then, almost touch, he seems to have argued, the islands of the Azores. Columbus' reading of the seer Salathiel-Ezra in the books of Esdras, from the Apocrypha (especially II Esdras 6:42, in which the prophet states that the Earth is six parts land to one of water) reinforced these ideas of the proportion of land- to sea-crossing, and the mistake was compounded by his idiosyncratic view of the length of a degree of geographic latitude. According to his reckoning, Zaiton, Marco Polo's great port of Cathay, would have lain a little to the east of present-day San Diego, Calif., U.S., and Cipango (Japan) on the meridian of the Virgin Islands. The latter were, of course, surprisingly, and confusingly, close to where Columbus actually made his landfalls.

The miscalculation of distance may have been willful on Columbus' part and made with an eye to his sponsors. The first journal suggests that Columbus may have been aware of his inaccuracy, for he consistently concealed from his sailors the number of actual miles they had covered, lest they become fearful for the journey back. Such economies with the truth may be evidence rather of bravery and the need to inspire confidence than of simple dishonesty or error. Columbus' other miscalculations were a little more serious, however. He declined, for instance, ever to admit that he had not found the true Indies and Cathay. Perhaps he genuinely believed that he had been there; but, at all events, this refusal to accept that he had discovered a brand new world in the Caribbean, in the face of mounting evidence that he had, both prevented his adapting his preformed plans and ideas to his actual experiences and dented his later reputation. Last, Columbus was autocratic to his sailors and remote from his companions and intending emigrants. He was thus a poor judge of the ambitions, and perhaps the failings, of those who sailed with him. This combination was to prove fatal to almost all of his hopes.

The ships for the first voyage, the *Niña, Pinta,* and *Santa María,* were fitted out at Palos, on the Tinto River in southern Spain. Santángel and Columbus' collaborators and suppliers in Palos (led by the shipowner Martín Alonso Pinzón, captain of the *Pinta*) provided at least 1,140,000 maravedis, and Columbus supplied more than a third of the sum contributed by the king and queen. Queen Isabella did not, then, have to pawn her jewels (a myth first put about by Las Casas). The little fleet left on Aug. 3, 1492. The admiral's navigational genius showed itself immediately, for they dropped down to the Canary Islands, off the northwest African mainland, rather than

sailing due west to the Azores. The westerlies prevailing in the Azores had defeated previous sailors to the west, but in the Canaries they could pick up the northeast trade winds, trusting to the westerlies for their return. After nearly a month in the Canaries the ships set out from San Sebastián de la Gomera on September 6. On October 12 land was sighted from the *Pinta* (though Columbus, on the *Niña,* later meanly claimed the privilege for himself). The place of the first Caribbean landfall is hotly disputed, but San Salvador, or Watling, Island is currently preferred to Samana Cay, Rum Cay, the Plana Cays, or the Turks and Caicos Islands. Beyond planting the royal banner, however, Columbus spent little time there, being anxious to press on to Cipango. He thought, on October 24, he had found it in Cuba, but by his journal entry of November 1 he had convinced himself that Cuba was the mainland of Cathay, though so far without evidence of great cities. Thus, on December 5, he turned back southeastward to search for the fabled city of Zaiton, missing Florida through this decision and, as it turned out, his sole chance of setting foot on the North American continent.

The first Caribbean landfall

The fleet was carried by adverse winds to Ayti (Haiti) on December 6, which Columbus renamed La Isla Española, or Hispaniola. He seems to have thought that Haiti might be Cipango or, if not Cipango, then perhaps one of the rich isles from which King Solomon's triennial fleet set sail so long ago, bringing gold and gems and spices back to Jerusalem for the king (I Kings 10:11, 22), or the biblical lands Sheba and Seba, confused by some commentators with the Tharsis and the isles of Psalm 71:10–11 in the Vulgate. Columbus found there at least enough gold and prosperity to save him from ridicule on his return to Spain. With the help of a cacique, or local Taino Indian chief, Guacanagarí, he set up a stockade on the northern coast of the island, named it La Navidad, and posted 39 men to guard it against his return. The accidental running aground of the *Santa María* provided additional planks and provisions for the garrison.

On Jan. 16, 1493, Columbus left with his remaining two ships for Spain. The journey back was a nightmare. Although the westerlies did indeed direct them homeward, in mid-February a terrible storm engulfed the fleet. The *Niña* was driven to seek harbour at Santa Maria in the Azores, and then, still storm-bound, to limp on to Lisbon. In Santa Maria a pilgrimage of thanksgiving to the shrine of the Virgin led to the temporary capture of 10 sailors by the hostile Portuguese authorities. An unavoidable interview with King John II in Lisbon left Columbus under the suspicion of collaborating with Spain's enemies. These events cast a shadow on his return to Palos.

Many of the tensions endemic to all Columbus' succeeding efforts had already made themselves felt on this first voyage. First and perhaps most damaging of all were those engendered by the incompatibility between the admiral's apparently high religious and even mystical aspirations and the realities of trading, competition, and colonization. Columbus never openly acknowledged this gulf and so was quite incapable of bridging it. He chose, for instance, in his reports, to interpret the grounding of the *Santa María* and the establishing of his fortress as events decreed by God. They were in fact deliberate and radical departures from the original simple project of exploration and contact, but Columbus preferred to justify them on religious rather than rational or economic grounds. (The admiral had begun even now to adopt a mode of sanctification in retrospect and validation through sheer force of autocratic personality that would make him so many enemies in the future.) Also, there had been looting, violence, and kidnapping, especially on Hispaniola. Columbus did control excesses, but he was determined to take back both material and human cargo to his sovereigns and for himself. This blunted his ability to retain the high moral ground. Further, the latent doubts about the foreigner Columbus' total loyalty to Spain had been revived, and, last, there were clear divisions in the ranks of Columbus' companions. Pinzón had disputed the route as the fleet reached the Bahamas and had sailed away from Cuba, and Columbus, on November 21. He rejoined him, with lame excuses, only on January 6. The *Pinta* made port at Bayona on its homeward journey, separately from Columbus and the *Niña*. Had Pinzón not died so soon after his return, Columbus' command of the second voyage might have been less than assured. As it was, the Pinzón family became now his rivals for reward.

Tension between Columbus and Pinzón

The second and third voyages. The gold, parrots, spices, and human captives Columbus displayed for his sovereigns at Barcelona convinced all of the need for a rapid second voyage. Columbus was now at the height of his popularity, and at least 17 ships set out from Cádiz on Sept. 25, 1493. Colonization and Christian evangelization were openly included this time in the plans, and a group of friars shipped with him. The presence of some 1,300 salaried men with perhaps 200 private investors and a small troop of cavalry are testimony to the expectations invested in the expedition. The confiscated properties of expelled Jews had swelled the royal coffers and probably largely financed it.

Sailing again via Gomera in the Canaries, the fleet took a more southerly course than on the first voyage and reached Dominica in the Lesser Antilles on Nov. 3, 1493. After sighting the Virgin Islands, it entered Samaná Bay in Hispaniola on November 23. Cuneo, deeply impressed by this unerring return, remarked that "since Genoa was Genoa there was never born a man so well equipped and expert in navigation as the said lord Admiral." An expedition to Navidad four days later, however, was shocked to find the fortress destroyed and the men dead. Here was a clear sign that native resistance had gathered strength. More fortified places were rapidly built, including a city, founded on January 2 and named La Isabela after the queen. On February 2 Antonio de Torres left La Isabela with 12 ships, a little gold, spices, parrots, captives (most of whom died en route), the bad news about Navidad, and some complaints about Columbus' methods of government. While Torres headed for Spain, two of Columbus' subordinates, Alonso de Ojeda and Pedro Margarit, took revenge for the massacre at Navidad and captured slaves, both seemingly with the admiral's full connivance. In March Columbus explored Cibao (thought to be the gold-bearing region of the island) and established the fortress of St. Thomas there. Then, late in April, three ships, led by Columbus in the *Niña,* explored the Cuban coastline and searched for gold in Jamaica, only to conclude that Hispaniola promised the richest spoils for the settlers. It was, the admiral decided, indeed the biblical Seba (Saba in the Vulgate), and Cuba was the mainland of Cathay. On June 12, 1494, Columbus insisted on a sworn declaration to that effect—a sure indication that, though not all of the company agreed with him, he was bent on insisting to his sovereign that he had reached Cathay.

The year 1495 saw the determined conquest of the island of Hispaniola and the beginning of troubles for the Taino Indians. There is evidence, especially in the objections of a friar, Bernardo Buil, that Columbus' methods remained harsh. The admiral's brothers, Bartholomew and Diego, were left in charge of the settlement when, on March 10, 1496, the admiral left La Isabela for Spain. He reached Cádiz on June 11 and immediately pressed his plans for a third voyage upon his sovereigns, at Burgos. Spain was at war now with France and in need of buying allies; moreover, the yield from the second voyage had fallen well short of the investment. But Portugal still threatened, and, though the two nations, in the Treaty of Tordesillas (June 7, 1494), had divided the Atlantic conveniently between themselves, they had as yet made no agreement about rights in the East. According to the treaty Spain might take all discovered land west of a line drawn from pole to pole 370 leagues west of the Cape Verde Islands and Portugal that to the east of the line; but what about the other side of the world, where West met East? Also, there might be a previously undiscovered antipodean continent; who, then, should be trusted to draw the line there? Ferdinand and Isabella therefore made a cautious further investment. Six ships left Sanlúcar de Barrameda on May 30, 1498, three filled with explorers and three with provisions for the settlement on Hispaniola. It was clear now that Columbus was expected both to find great prizes and to establish the flag of Spain firmly in the East.

Certainly he found prizes, but not, sadly, quite of the

Aim of the third voyage

kind his sponsors required. The aim this time was to explore to the south of the existing discoveries, in the hope of finding both a strait from Cuba/Cathay to India and, perhaps, the unknown antipodean continent. Thus, on June 21, the provision ships left Gomera for Hispaniola, while the explorers headed south for the Cape Verde Islands. Columbus began the Atlantic crossing on July 4, 1498, from São Tiago Island in Cape Verde. He discovered the principle of compass variation (the variation at any point on the Earth's surface between the direction to magnetic and geographic north), for which he made brilliant allowance on the journey from Margarita Island to Hispaniola on the later leg of this voyage, and he also observed, though misunderstood, the diurnal rotation of the Pole Star. After stopping at Trinidad (named after the Holy Trinity, whose protection he had invoked for the voyage), Columbus entered the Gulf of Paria and planted the Spanish flag on the Paria Peninsula in Venezuela. He sent the caravel *El Corréo* southward to investigate the mouth of the Rio Grande (the northern branch of the Orinoco), and by Aug. 15, 1498, knew by the great floods of fresh water flowing into the Gulf of Paria that he had discovered another continent—"another world." But he did not find the strait to India, nor did he find those mines of King Solomon's gold his reading had led him and his sovereigns to expect in these latitudes; and he made only disastrous discoveries when he returned to Hispaniola.

Rebellion on Hispaniola

The rule of his brothers, Bartholomew and Diego, had been resented there, by both the native inhabitants and the immigrants. A rebellion by the alcalde (mayor) of La Isabela, Francisco Roldán, had led to appeals to the Spanish court, and, even as Columbus attempted to restore order (partly, it must be said, by hangings), the Spanish chief justice, Francisco de Bobadilla, was on his way out to the colony with a commission from the sovereigns to investigate all the complaints. It is hard to explain exactly what the trouble was. Columbus' report to his sovereigns from the second voyage, taken back by Torres and so known as the Torres Memorandum, speaks of sickness, poor provisioning, recalcitrant natives, and undisciplined hidalgos (gentry). It may be that these problems had intensified. But the Columbus family's repressive policies must be held at least partly responsible, intent as it undoubtedly now was on enslaving the native population, both to work the placer mines of Hispaniola and for export to Europe. The adelantado (governor) Bartholomew Columbus had replaced Columbus' original system of gold production, whereby the local chiefs had been in charge of delivering gold on a loose per capita basis, by direct exploitation through favoured Spaniards, and this had caused widespread dissent among both unfavoured Spaniards and indigenous chiefs. Certainly Bobadilla found against the Columbus family when he arrived in Hispaniola. He clapped Columbus and his two brothers in irons and sent them promptly back, on the *La Gorda,* to Cádiz. They arrived there in late October 1500.

The long letter Columbus composed on the journey back and sent to his sovereigns immediately on his return is one of the most extraordinary he wrote, and one of the most informative. One part of its exalted, almost mystical, quality may be attributed to the humiliations the admiral had endured (humiliations he compounded by refusing to allow the captain of the *La Gorda* to remove his chains during the voyage) and another to the fact that he was now suffering severely from sleeplessness, eyestrain, and a form of rheumatoid arthritis, which may have hastened his death. Much of what he said in the letter, however, seems genuinely to have expressed his beliefs. One can learn from it that Columbus had absolute faith in his navigational abilities, his seaman's sense of the weather, his eyes, and his reading. The last is apparent in his

The outer region of the Earthly Paradise

conviction that he had reached the outer region of the Earthly Paradise. Thus, as he approached Trinidad and the Paria Peninsula, the rotation of the Pole Star gave him, he wrote, the impression that the fleet was climbing. The weather had become extremely mild, and the flow of fresh water into the Gulf of Paria was, as he saw, enormous. All this could have one explanation only—they had mounted toward the temperate heights of the Earthly Paradise, heights from which the rivers of Paradise ran into the sea. Columbus had found all such signs of the outer regions of the Earthly Paradise in his reading, and indeed they were widely known. He was, then, on this estimate, close to the realms of gold that lay near Paradise. He had not found the gold yet, to be sure; but he knew now where it was. Columbus' expectations thus allowed him again to interpret his discoveries in terms of biblical and classical sources and to do so in a manner that would be comprehensible to his sponsors and favourable to himself.

This letter, desperate though it was, convinced the sovereigns that, even if he had not yet found the prize, he had been close to it after all. They ordered his release and gave him audience at Granada in late December 1500. They accepted that, although Columbus' capacities as governor were wanting (on Sept. 3, 1501, they appointed Nicolás de Ovando, not Columbus, to succeed Bobadilla to the governorship), those as navigator and explorer were not. Columbus, even ill and importunate, was a better investment than the many adventurers and profiteers who had meantime been licensed to compete with him, and there was always the danger (revealed in some of the letters of this period) that he would offer his services to his native Genoa. In October 1501, then, Columbus went to Seville to make ready his fourth and final expedition.

The fourth voyage and death of the admiral. The winter and spring of 1501–02 were exceedingly busy. The four chosen ships were bought, fitted, and crewed, and some 20 of Columbus' extant letters and memoranda were written then, many in exculpation of Bobadilla's charges, others pressing even harder the nearness of the Earthly Paradise and the need to reconquer Jerusalem. Columbus took to calling himself "Christbearer" in his letters and to using a strange and mystical signature, never satisfactorily explained. He began also, with all these thoughts and pressures in mind, to compile both his Book of Privileges and his Book of Prophecies. The first, in defending the titles and financial claims of the Columbus family, seems oddly annexed to the Christian apocalypticism of the second; yet both were linked most closely in the admiral's own mind. He seems to have been certain that his mission was divinely guided. Thus, the loftiness of his spiritual aspirations increased as the threats to his personal ones mounted. In the midst of all these efforts and hazards, Columbus sailed from Cádiz on his fourth voyage on May 9, 1502.

The four ships allowed him contrasted sharply with the thirty granted to the governor of Hispaniola, Ovando. The confidence his sovereigns had formerly had in Columbus had now diminished, and there is much to suggest that pity mingled with hope in their support. His illnesses were worsening, and the hostility to his rule in Hispaniola was unabated. Thus, Ferdinand and Isabella forbade him to return there. He was to resume, instead, his interrupted exploration of the "other world" to the south that he had found on his third voyage and to look most particularly for gold and the strait to India. Columbus expected to meet the Portuguese navigator Vasco da Gama in the East, and the sovereigns instructed him on the appropriate courteous behaviour for such a meeting—another sign, perhaps, that they did not wholly trust him. They were right. He departed from Gran Canaria on the night of May 25, made landfall at Martinique on June 15 (after the fastest crossing to date), and was, by June 29, demanding entrance to Santo Domingo on Hispaniola. Only on being refused such entry by Ovando did he take to the farther west and the south. July to September 1502 saw him coasting Jamaica, the southern shore of Cuba, Honduras, and the Mosquito Coast of Nicaragua. The feat of Caribbean transnavigation, which took him to Bonacca Island off Cape Honduras on July 30, deserves to be reckoned on a par, as to difficulty, with that of crossing the Atlantic, and the admiral was justly proud of it. Constantly probing for the strait, the fleet sailed round the Chiriquí Lagoon (in Panama) in October, then, searching for gold, along Veragua and Panama in the foulest of weather. In February 1503 Columbus attempted to establish a trading post at Santa María de Belén on the bank of the Belén (Bethlehem) River under the command of Bartholomew Colum-

bus in order to exploit the promising gold yield he was beginning to find in Veragua. Indian hostility and the poor condition of his ships (of which only two now remained, and these fearfully holed by shipworm) determined him, however, to turn back to Hispaniola. On this voyage the ultimate disaster struck. Against Columbus' (right) judgment, the pilots turned the fleet north too soon. The ships could not make the distance and had to be beached on the coast of Jamaica. By June 1503 Columbus and his crews were castaways.

Castaways

Columbus had hoped, as he said to his sovereigns, that "my hard and troublesome voyage may yet turn out to be my noblest"; it was in fact the most disappointing of all and the most unlucky. In its searches for the strait and for gold the fleet had missed discovering the Pacific and making contact with the great Mayan empire of Yucatán by the narrowest of margins. Also, though two of the men (Diego Méndez and Bartolomeo Fieschi, captains of the wrecked ships *La Capitana* and *Vizcaíno,* respectively) left about July 17 to get help for the castaways, traversing the 450-mile journey to Hispaniola safely by canoe, Ovando made no great haste to deliver that help. In the meantime, the admiral displayed his acumen once again by correctly predicting an eclipse of the Moon from his astronomical tables, thus frightening the natives into providing food; but it was June 1504 before rescue came, and Columbus and his men did not reach Hispaniola until August 13 of the same year. On November 7 he sailed back into Sanlúcar, to find that Queen Isabella had made her will and was dying.

It would be wrong to suppose that Columbus spent his final two years wholly in illness, poverty, and oblivion. His son Diego was well established at court, and the admiral himself lived in Seville in some style. His "tenth" of the gold diggings in Hispaniola, guaranteed in 1493, provided a substantial revenue (against which his Genoese bankers allowed him to draw), and one of the few ships to escape a hurricane off Hispaniola in 1502 (in which Bobadilla himself went down) was that carrying Columbus' gold. He felt himself ill-used and short-changed nonetheless, and these years were marred, for both him and King Ferdinand, by his constant pressing for redress. He followed the court from Segovia to Salamanca and Valladolid, attempting to gain an audience. He knew that his life was nearing its end, and in August 1505 he began to add codicils to his will. He died on May 20, 1506. First he was laid in the Franciscan friary in Valladolid, then taken to the family mausoleum established at the Carthusian monastery of Las Cuevas in Seville. Finally, by the will of his son Diego, Columbus' bones were laid with his own in the Cathedral of Santo Domingo, Hispaniola.

THE DEBATE

The debate about Columbus' character and achievements began at least as early as the first rebellion of the Taino Indians and continued with Roldán, Bobadilla, and Ovando. It has been revived periodically (notably by Las Casas and Jean-Jacques Rousseau) ever since. The Columbus quincentenary of 1992 rekindled the intensity of this early questioning and redirected its aims, often profitably. The word "encounter" is now preferred to "discovery" when describing the contacts between the Old World and the New, and more attention has come to be paid to the fate of the Native American peoples and to the sensibilities of non-Christians. Enlightening discoveries have been made about the diseases that reached the New World through Columbus' agency as well as those his sailors took back with them to the Old. The pendulum may, however, now have swung too far. Columbus has been made a whipping boy for events far beyond his own reach or knowledge and a means to an agenda of condemnation that far outstrips his own guilt. Thus, too little attention has recently been paid to the historical circumstances that conditioned him. His obsessions with lineage and imperialism, his seemingly bizarre Christian beliefs, and his apparently brutal behaviour come from a world remote from that of modern democratic ideas, it is true; but it was the world to which he belonged. The forces of European expansion, with their slaving and search for gold, had been unleashed before him and were at his time quite beyond his control. Columbus simply decided to be in the vanguard of them. He succeeded. Columbus' towering stature as a seaman and navigator, the sheer power of his religious convictions (self-delusory as they sometimes were), his personal magnetism, his courage, his endurance, his determination, and, above all, his achievements as an explorer, should continue to be recognized.

BIBLIOGRAPHY. Editions of Columbus' writings include CECIL JANE (trans. and ed.), *Select Documents Illustrating the Four Voyages of Columbus,* 2 vol. (1930–33, reprinted 1967); SAMUEL ELIOT MORISON (trans. and ed.), *Journals and Other Documents on the Life and Voyages of Christopher Columbus* (1963); J.M. COHEN (ed. and trans.), *The Four Voyages of Christopher Columbus* (1969, reissued 1988), comprising his logbook, letters, dispatches, and other material; ANTONIO RUMEU DE ARMAS, *Libro Copiador de Cristóbal Colón,* 2 vol. (1989), which includes a transcription of a 16th-century copybook containing several letters from Columbus; DELNO C. WEST and AUGUST KLING (trans. and ed.), *The Libro de las Profecías of Christopher Columbus* (1991), with a concise biographical introduction; and CONSUELO VARELA (ed.), *Textos y documentos completos,* 2nd ed. (1992). DAVID HENIGE, *In Search of Columbus: The Sources for the First Voyage* (1991), is a scholarly textual criticism of what is known as Columbus' logbook; the author concludes that it cannot be used with any certainty to identify Columbus' first landfall. MARGARITA ZAMORA, *Reading Columbus* (1993), comprises translations of crucial texts with comments on them. SILVIO A. BEDINI (ed.), *The Christopher Columbus Encyclopedia,* 2 vol. (1992), is a useful reference work. FERNANDO COLÓN, *The Life of the Admiral Christopher Columbus,* trans. by BENJAMIN KEEN, 2nd ed. (1992), by Columbus' son, has been used as source material for later biographies. Among modern English-language biographies are the classic work by SAMUEL ELIOT MORISON, *Admiral of the Ocean Sea: A Life of Christopher Columbus,* 2 vol. (1942, reissued 1962), chatty and discursive but unrivaled in close detail and navigational expertise, also available in a 1-vol. condensed ed. with the same title but lacking the scholarly apparatus (1942, reprinted 1991); FELIPE FERNÁNDEZ-ARMESTO, *Columbus* (1991), arguably one of the best-written and most historically sensitive biographies; and PAOLO EMILIO TAVIANI, *Columbus: The Great Adventure: His Life, His Times, and His Voyages,* trans. from Italian (1991), a popularized but well-informed panegyric.

Studies of various aspects of Columbus' voyages and their impact include VALERIE I.J. FLINT, *The Imaginative Landscape of Christopher Columbus* (1992), concentrating on the late-medieval past in which the admiral's conceptions of geography and morality were rooted; JAMES R. MCGOVERN (ed.), *The World of Columbus* (1992), essays on art, science, music, and navigation; WILLIAM F. KEEGAN, *The People Who Discovered Columbus* (1992), on the fate of Lucayan life on the Bahamas; IRVING ROUSE, *The Tainos: Rise & Decline of the People Who Greeted Columbus* (1992), a temperate and balanced description; SAMUEL M. WILSON, *Hispaniola: Caribbean Chiefdoms in the Age of Columbus* (1990), on the character and destruction of Taino culture; JAMES AXTELL, *Beyond 1492: Encounters in Colonial North America* (1992), which pays particular attention to the effect of the first encounters on the native populations; JERALD T. MILANICH and SUSAN MILBRATH (eds.), *First Encounters: Spanish Explorations in the Caribbean and the United States, 1492–1570* (1989), an excellent introduction to the archaeological evidence; J. DANIEL ROGERS and SAMUEL M. WILSON (eds.), *Ethnohistory and Archaeology: Approaches to Postcontact Change in the Americas* (1993); JOHN W. VERANO and DOUGLAS H. UBELAKER (eds.), *Disease and Demography in the Americas* (1992); ANTHONY PAGDEN, *European Encounters with the New World: From Renaissance to Romanticism* (1993), exploring European reactions to the expansion; and BERNARD LEWIS, *Cultures in Conflict: Christians, Muslims, and Jews in the Age of Discovery* (1995).

The debate over Columbus' achievements is taken up in NOBLE DAVID COOK and W. GEORGE LOVELL (eds.), *Secret Judgments of God: Old World Disease in Colonial Spanish America* (1991), on the disastrous effects on the native peoples; ROBERT ROYAL, *1492 and All That: Political Manipulations of History* (1992), an attempt to redress the balance, but very much a present-day approach; RAY GONZÁLEZ (ed.), *Without Discovery: A Native Response to Columbus* (1992), an anti-European treatment; and JOHN YEWELL, CHRIS DODGE, and JAN DESIREY (eds.), *Confronting Columbus: An Anthology* (1992), from the perspective of Native Americans.

Combinatorics and Combinatorial Geometry

Combinatorics and combinatorial geometry are concerned with arrangements of mathematical elements, problems of selection or choice, permutations and combinations, and certain aspects of the theory of probability. The fundamental concepts and methods of these two closely related fields of mathematics are treated in this article, as are the factors that led to their development. (Ed.)

The article is divided into the following sections:

Combinatorics

The scope of combinatorics is hard to define with any exactitude. In general, however, it may be said that it is concerned with arrangements, operations, and selections within a finite or a discrete system.

The problems studied with combinatorics

One of the basic problems is to determine the number of possible configurations (*e.g.*, graphs, designs, arrays) of a given type. Even when the rules specifying the configuration are relatively simple, enumeration may sometimes present formidable difficulties. The mathematician may have to be content with finding an approximate answer or at least a good lower and upper bound.

In mathematics, generally, an entity is said to "exist" if a mathematical example satisfies the abstract properties that define the entity. In this sense it may not be apparent that even a single configuration with certain specified properties exists. This situation gives rise to problems of existence and construction. There is again an important class of theorems that guarantee the existence of certain choices under appropriate hypotheses. Besides their intrinsic interest, these theorems may be used as existence theorems in various combinatorial problems.

Finally, there are problems of optimization. As an example, a function f, the economic function, assigns the numerical value $f(x)$ to any configuration x with certain specified properties. In this case the problem is to choose a configuration x_0 that minimizes $f(x)$ or makes it $\varepsilon =$ minimal—that is, for any number $\varepsilon > 0$, $f(x_0) \leq f(x) + \varepsilon$, for all configurations x, with the specified properties.

HISTORY

Early developments. Certain types of combinatorial problems have attracted the attention of mathematicians since early times. Magic squares, for example, which are square arrays of numbers with the property that the rows, columns, and diagonals add up to the same number, occur in the *I Ching*, a Chinese book dating back to the 12th century BC. The binomial coefficients, or integer coefficients in the expansion of $(a+b)^n$, were known to the 12th-century Indian mathematician Bhāskara, who in his *Līlāvatī* ("The Graceful"), dedicated to a beautiful woman, gave the rules for calculating them together with illustrative examples. "Pascal's triangle," a triangular array of binomial coefficients, had been taught by the 13th-century Persian philosopher Naṣīr ad-Dīn aḷ-Ṭūsī.

In the West, combinatorics may be considered to begin in the 17th century with Blaise Pascal and Pierre de Fermat, both of France, who discovered many classical combinatorial results in connection with the development of the theory of probability. The term combinatorial was first used in the modern mathematical sense by the German philosopher and mathematician Gottfried Wilhelm Leibniz in his *Dissertatio de Arte Combinatoria* ("Dissertation Concerning the Combinational Arts"). He foresaw the applications of this new discipline to the whole range of the sciences. The Swiss mathematician Leonhard Euler was finally responsible for the development of a school of authentic combinatorial mathematics beginning in the 18th century. He became the father of graph theory when he settled the Königsberg bridge problem, and his famous conjecture on Latin squares was not resolved until 1959.

Combinatorics before 1920

In England, Arthur Cayley, near the end of the 19th century, made important contributions to enumerative graph theory, and James Joseph Sylvester discovered many combinatorial results. The British mathematician George Boole at about the same time used combinatorial methods in connection with the development of symbolic logic, and the combinatorial ideas and methods of Henri Poincaré, which developed in the early part of the 20th century in connection with the problem of n bodies, have led to the discipline of topology, which occupies the centre of the stage of mathematics. Many combinatorial problems were posed during the 19th century as purely recreational problems and are identified by such names as "the problem of eight queens" and "the Kirkman school girl problem." On the other hand, the study of triple systems begun by Thomas P. Kirkman in 1847 and pursued by Jakob Steiner, a Swiss-born German mathematician, in the 1850s was the beginning of the theory of design. Among the earliest books devoted exclusively to combinatorics are the German mathematician Eugen Netto's *Lehrbuch der Combinatorik* (1901; "Textbook of Combinatorics") and the British mathematician Percy Alexander MacMahon's *Combinatory Analysis* (1915–16), which provide a view of combinatorial theory as it existed before 1920.

Combinatorics during the 20th century. Many factors have contributed to the quickening pace of development of combinatorial theory since 1920. One of these was the development of the statistical theory of the design

of experiments by the English statisticians Ronald Fisher and Frank Yates, which has given rise to many problems of combinatorial interest; the methods initially developed to solve them have found applications in such fields as coding theory. Information theory, which arose around midcentury, has also become a rich source of combinatorial problems of a quite new type.

Another source of the revival of interest in combinatorics is graph theory, the importance of which lies in the fact that graphs can serve as abstract models for many different kinds of schemes of relations among sets of objects. Its applications extend to operations research, chemistry, statistical mechanics, theoretical physics, and socioeconomic problems. The theory of transportation networks can be regarded as a chapter of the theory of directed graphs. One of the most challenging theoretical problems, the four-colour problem (see below) belongs to the domain of graph theory. It has also applications to such other branches of mathematics as group theory.

The development of computer technology in the second half of the 20th century is a main cause of the interest in finite mathematics in general and combinatorial theory in particular. Combinatorial problems arise not only in numerical analysis but also in the design of computer systems and in the application of computers to such problems as those of information storage and retrieval.

Statistical mechanics is one of the oldest and most productive sources of combinatorial problems. Much important combinatorial work has been done by applied mathematicians and physicists since the mid-20th century—for example, the work on Ising models (see below *The Ising problem*).

Use of combinatorics in pure mathematics

In pure mathematics, combinatorial methods have been used with advantage in such diverse fields as probability, algebra (finite groups and fields, matrix and lattice theory), number theory (difference sets), set theory (Sperner's theorem), and mathematical logic (Ramsey's theorem).

In contrast to the wide range of combinatorial problems and the multiplicity of methods that have been devised to deal with them stands the lack of a central unifying theory. Unifying principles and cross connections, however, have begun to appear in various areas of combinatorial theory. The search for an underlying pattern that may indicate in some way how the diverse parts of combinatorics are interwoven is a challenge that faces mathematicians in the last quarter of the 20th century.

PROBLEMS OF ENUMERATION

Permutations and combinations. *Binomial coefficients.* An ordered set $a_1, a_2, \ldots, a_r$ of r distinct objects selected from a set of n objects is called a permutation of n things taken r at a time. The number of permutations is given by ${}_nP_n = n(n-1)(n-2)\cdots(n-r+1)$. When $r=n$, the number ${}_nP_r = n(n-1)(n-2)\cdots$ is simply the number of ways of arranging n distinct things in a row. This expression is called factorial n and is denoted by $n!$. It follows that ${}_nP_r = n!/(n-r)!$. By convention $0! = 1$.

A set of r objects selected from a set of n objects without regard to order is called a combination of n things taken r at a time. Because each combination gives rise to $r!$ permutations, the number of combinations, which is written $\binom{n}{r}$, can be expressed in terms of factorials (see Box, formula 1).

The number $\binom{n}{r}$ is called a binomial coefficient because it occurs as the coefficient of $p^r q^{n-r}$ in the binomial expansion—that is, the re-expression of $(q+p)^n$ in a linear combination of products of p and q (see 2).

If $0 \leqslant p \leqslant 1$, and $q = 1-p$, then the term $\binom{n}{r} p^r q^{n-r}$ in the binomial expansion is the probability that an event the chance of occurrence of which is p occurs exactly r times in n independent trials (see PROBABILITY THEORY).

The answer to many different kinds of enumeration problems can be expressed in terms of binomial coefficients. The number of distinct solutions of the equation $x_1 + x_2 + \cdots + x_n = m$, for example, in which m is a non-negative integer $m \geqslant n$ and in which only non-negative integral values of x_i are allowed is expressible this way, as was found by the 17th–18th-century French-born British mathematician Abraham De Moivre (see 3).

Multinomial coefficients. If S is a set of n objects, and $n_1, n_2, \ldots, n_k$ are non-negative integers satisfying $n_1 + n_2 + \cdots + n_k = n$, then the number of ways in which the objects can be distributed into k boxes, $X_1, X_2, \ldots, X_k$, such that the box X_i contains exactly n_i objects is given in terms of a ratio constructed of factorials (see 4). This number, called a multinomial coefficient, is the coefficient in the multinomial expansion of the nth power of the sum of the $\{p_i\}$ (see 5). If all of the $\{p_i\}$ are non-negative and sum to 1 and if there are k possible outcomes in a trial in which the chance of the ith outcome is p_i, then the ith summand in the multinomial expansion is the probability that in n independent trials the ith outcome will occur exactly n_i times, for each i, $1 \leqslant i \leqslant k$.

Recurrence relations and generating functions. If f_n is a function defined on the positive integers, then a relation that expresses f_{n+k} as a linear combination of function values of integer index less than $n+k$, in which a fixed constant in the linear combination is written a_i, is called a recurrence relation (see 6). The relation together with the initial values $f_0, f_1, \ldots, f_{k-1}$ determines f_n for all n. The function $F(x)$ constructed of a sum of products of the type $f_n x^n$, the convergence of which is assumed in the neighbourhood of the origin, is called the generating function of f_n (see 7).

Generating functions

The set of the first n positive integers will be written X_n. It is possible to find the number of subsets of X_n containing no two consecutive integers, with the convention that the null set counts as one set. The required number will be written f_n. A subset of the required type is either a subset of X_{n-1} or is obtained by adjoining n to a subset of X_{n-2}. Therefore f_n is determined by the recurrence relation $f_n = f_{n-1} + f_{n-2}$ with the initial values $f_0 = 1$, $f_1 = 2$. Thus $f_2 = 3$, $f_3 = 5$, $f_4 = 8$, and so on. The generating function $F(x)$ of f_n can be calculated (see 8), and from this a formula for the desired function f_n can be obtained (see 9). That $f_n = f_{n-1} + f_{n-2}$ can now be directly checked.

Partitions. A partition of a positive integer n is a representation of n as a sum of positive integers $n = x_1 + x_2 + \cdots + x_k$, $x_i \geqslant 1$, $i = 1, 2, \ldots, k$. The numbers x_i are called the parts of the partition. The number of ordered partitions into k parts is $\binom{n-1}{k-1}$, for this is the number of ways of putting $k-1$ separating marks in the $n-1$ spaces between n dots in a row. The theory of unordered partitions is much more difficult and has many interesting features. An unordered partition can be standardized by listing the parts in a decreasing order. Thus $n = x_1 + x_2 + \cdots + x_k$, $x_1 \geqslant x_2 \geqslant \cdots \geqslant x_k \geqslant 1$. In what follows partition will mean an unordered partition.

The number of partitions of n into k parts will be denoted by $P_k(n)$, and a recurrence formula for it can be obtained from the definition (see 10). This recurrence formula, together with the initial conditions $P_k(n) = 0$ if $n < k$, and $P_k(k) = 1$ determines $P_k(n)$. It can be shown that $P_k(n)$ depends on the value of n (mod $k!$), in which the notation $x \equiv a \pmod{b}$ means that x is any number that, if divided by b, leaves the same remainder as a does. For example, $P_3(n) = n^2 + c_n$, in which $c_n = 0, -1/12, -1/3, +1/4, -1/3$, or $-1/12$, according as n is congruent to 0, 1, 2, 3, 4, or 5 (mod 6). $P(n)$, which is a sum over all values of k from 1 to n of $P_k(n)$, denotes the number of partitions of n into n or fewer parts.

Many results on partitions can be obtained by the use of Ferrers' diagram. The diagram of a partition is obtained by putting down a row of squares equal in number to the largest part, then immediately below it a row of squares equal in number to the next part, and so on. Such a diagram for $14 = 5+3+3+2+1$ is shown in Figure 1.

Ferrers' partitioning diagram

By rotating the Ferrers' diagram of the partition about the diagonal, it is possible to obtain from the partition $n = x_1 + x_2 + \cdots + x_k$ the conjugate partition $n = x_1^* + x_2^* + \cdots x_n^*$, in which x_i^* is the number of parts in the original partition of cardinality i or more.

(1) $\binom{n}{r} = \frac{{}_nP_r}{r!} = \frac{n!}{r!(n-r)!}$

(2) $(q+p)^n = q^n + \binom{n}{1}pq^{n-1} + \cdots + \binom{n}{r}p^r q^{n-r} + \cdots + p^n$

(3) $N = \binom{m+n-1}{n-1} = \frac{(m+n-1)!}{(n-1)!m!}$

(4) $\binom{n}{n_1, n_2, \cdots, n_k} = \frac{n!}{n_1!n_2! \cdots n_k!}$

(5) $(p_1 + p_2 + \cdots + p_k)^n = \sum \binom{n}{n_1, n_2, \cdots, n_k} p_1^{n_1} p_2^{n_2} \cdots p_k^{n_k}$
The summation is over all non-negative $n_1, n_2, \cdots, n_k$ for which $n_1 + n_2 + \cdots + n_k = n$.

(6) $f_{n+k} = a_1 f_{n+k-1} + a_2 f_{n+k-2} + \cdots + a_k f_n$

(7) $F(x) = \sum_{n=0}^{\infty} f_n x^n$

(8) $F(x) = \frac{1+x}{1-x(1+x)}$

(9) $f_n = \sum_k \binom{n+1-k}{k}$
The summation extends over all values of k from 0 to the largest integer not exceeding $(n+1)/2$.

(10) $P_k(n) = P_k(n-k) + P_{k-1}(n-k) + \cdots + P_1(n-k)$

Thus the conjugate of the partition of 14 already given is $14 = 5+4+3+1+1$. Hence, the following result is obtained:

(F_1) The number of partitions of n into k parts is equal to the number of partitions of n with k as the largest part.

Other results obtainable by using Ferrers' diagrams are:

(F_2) The number of self-conjugate partitions of n equals the number of partitions of n with all parts unequal and odd.

(F_3) the number of partitions of n into unequal parts is equal to the number of partitions of n into odd parts.

Generating functions can be used with advantage to study partitions. For example, it can be proved that:

(G_1) The generating function $F_1(x)$ of $P(n)$, the number of partitions of the integer n, is a product of reciprocals of terms of the type $(1-x^k)$, for all positive integers k, with the convention that $P(0) = 1$ (see 11).

(G_2) The generating function $F_2(x)$ of the number of partitions of n into unequal parts is a product of terms like $(1+x^k)$, for all positive integers k (see 12).

(G_3) The generating function $F_3(x)$ of the number of partitions of x consisting only of odd parts is a product of reciprocals of terms of the type $(1-x^k)$, for all positive odd integers k (see 13).

Thus to prove (F_3) it is necessary only to show that the generating functions described in (G_2) and (G_3) are equal. This method was used by Euler.

The principle of inclusion and exclusion: derangements. For a case in which there are N objects and n properties $A_1, A_2, \cdots A_n$, the number $N(A_1, A_2)$, for example, will be the number of objects that possess the properties A_1, A_2. If $N(\bar{A}_1, \bar{A}_2, \cdots, \bar{A}_n)$ is the number of objects possessing none of the properties $A_1, A_2, \cdots, A_n$, then this number can be computed as an alternating sum of sums involving the numbers of objects that possess the properties (see 14). This is the principle of inclusion and exclusion expressed by Sylvester.

Sylvester principle

The permutation of n elements that displaces each object is called a derangement. The permutations themselves may be the objects and the property i may be the property that a permutation does not displace the ith element. In such a case $N = n!$ and $N(A_1, A_2) = (n-2)!$, for example. Hence the number D_n of derangements can be shown to be approximated by $n!/e$ (see 15). This number was first obtained by Euler. If n persons check their hats in a restaurant, and the waiter loses the checks and returns the hats at random, the chance that no one receives his own hat is $D_n/n! = e^{-1}$ approximately. It is surprising that the approximate answer is independent of n. To six places of decimals $e^{-1} = 0.367879$. When $n = 6$ the error of approximation is less than 0.0002.

If n is expressed as the product of powers of its prime factors $p_1, p_2, \cdots p_k$, and if the objects are the integers less than or equal to n, and if A_i is the property of being divisible by p_i, then Sylvester's formula gives, as the number of integers less than n and prime to it, a function of n, written $\varphi(n)$, composed of a product of n and k factors of the type $(1 - 1/p_i)$ (see 16). The function $\varphi(n)$ is the Euler function.

Polya's theorem. It is required to make a necklace of n beads out of an infinite supply of beads of k different colours. The number of different necklaces, $c(n, k)$, that can be made is given by the reciprocal of n times a sum of terms of the type $\varphi(n)\, k^{n/d}$, in which the summation is over all divisors d of n and φ is the Euler function (see 17).

Though the problem of the necklaces appears to be frivolous, the formula given above can be used to solve a difficult problem in the theory of Lie algebras, of some importance in modern physics.

The general problem of which the necklace problem is a special case was solved by the Hungarian-born U.S. mathematician George Polya in a famous 1937 memoir in which he established connections between groups, graphs, and chemical bonds. It has been applied to enumeration problems in physics, chemistry, and mathematics.

The Möbius inversion theorem. In 1832 the German astronomer and mathematician August Ferdinand Möbius proved that, if f and g are functions defined on the set of positive integers, such that f evaluated at x is a sum of values of g evaluated at divisors of x, then inversely g at x can be evaluated as a sum involving f evaluated at divisors of x (see 18).

In 1964 the U.S. mathematician Gian-Carlo Rota obtained a powerful generalization of this theorem, providing a fundamental unifying principle of enumeration. One consequence of Rota's theorem is the following:

Rota's theorem

If f and g are functions defined on subsets of a finite set A, such that $f(A)$ is a sum of terms $g(S)$, in which S is a subset of A, then $g(A)$ can be expressed in terms of f (see 19).

$$(11)\quad F_1(x)=(1-x)^{-1}(1-x^2)^{-1}(1-x^3)^{-1}\cdots$$

$$(12)\quad F_2(x)=(1+x)(1+x^2)(1+x^3)\cdots$$

$$(13)\quad F_3(x)=(1-x)^{-1}(1-x^3)^{-1}(1-x^5)^{-1}\cdots$$

$$(14)\quad \begin{cases} N(\bar{A}_1,\bar{A}_2,\cdots,\bar{A}_n) \\ \quad =N-\sum N(A_{i_1})+\sum N(A_{i_1},A_{i_2})+\cdots+ \\ \qquad +(-1)^k\sum N(A_{i_1},A_{i_2},\cdots,A_{i_k})+\cdots+ \\ \qquad +(-1)^n N(A_1,A_2,\cdots,A_n) \\ \text{In the general term the summation is over all} \\ \text{combinations of } k \text{ properties from the set of } n \\ \text{properties} \quad A_1,A_2,\cdots,A_n. \end{cases}$$

$$(15)\quad \begin{cases} D_n=n!-\binom{n}{1}(n-1)!+\cdots+(-1)^k\binom{n}{k}(n-k)!+ \\ \qquad +\cdots+(-1)^n\binom{n}{n} \\ \quad =n!\left(1-\frac{1}{1!}+\frac{1}{2!}+\cdots+(-1)^k\frac{1}{k!}+\right. \\ \qquad \left.+\cdots+(-1)^n\frac{1}{n!}\right) \\ \quad =n!/e \quad \text{approximately.} \end{cases}$$

$$(16)\quad \phi(n)=n\left(1-\frac{1}{p_1}\right)\left(1-\frac{1}{p_2}\right)\cdots\left(1-\frac{1}{p_k}\right)$$

$$(17)\quad c(n,k)=\frac{1}{n}\sum_{d|n}\phi(d)k^{n/d}$$

$$(18)\quad \begin{cases} \text{If} \quad f(x)=\sum_{d|x} g(d), \\ \text{in which } d|x \text{ means that } d \text{ is a divisor of } x, \text{ then} \\ g(x)=\sum_{d|x}\mu(d,x)f(d), \\ \text{in which} \\ \mu(d,n)=\begin{cases} 1 & \text{if } n=d \\ (-1)^k & \text{if } n=p_1p_2\cdots p_k d \\ 0 & \text{otherwise.} \end{cases} \end{cases}$$

Special problems. Despite the general methods of enumeration already described, there are many problems in which they do not apply and which therefore require special treatment. Two of these are described below, and others will be met further in this article.

The Ising problem. A rectangular $m \times n$ grid is made up of unit squares, each coloured either red or green. How many different colour patterns are there if the number of boundary edges between red squares and green squares is prescribed?

This problem, though easy to state, proved very difficult to solve. A complete and rigorous solution was not achieved until the early 1960s. The importance of the problem lies in the fact that it is the simplest model that exhibits the macroscopic behaviour expected from certain natural assumptions made at the microscopic level. Historically, the problem arose from an early attempt, made in 1925, to formulate the statistical mechanics of ferromagnetism.

The three-dimensional analogue of the Ising problem remains unsolved in spite of persistent attacks.

Non-self-intersecting random walk. A random walk consists of a sequence of n steps of unit length on a flat rectangular grid, taken at random either in the x- or the y-direction, with equal probability in each of the four directions. What is the number R_n of random walks that do not touch the same vertex twice? This problem has defied solution, except for small values of n, though a large amount of numerical data has been amassed.

PROBLEMS OF CHOICE

Systems of distinct representatives. Subsets $S_1, S_2, \cdots, S_n$ of a finite set S are said to possess a set of distinct representatives if $x_1, x_2, \cdots, x_n$ can be found, such that $x_i \in S_i$, $i=1, 2, \cdots, n$, $x_i \neq x_j$ for $i \neq j$. It is possible that S_i and S_j, $i \neq j$, may have exactly the same elements and are distinguished only by the indices i, j. In 1935 a mathematician, M. Hall, Jr., of the United States, proved that a necessary and sufficient condition for $S_1, S_2, \cdots, S_n$ to possess a system of distinct representatives is that, for every $k \leq n$, any k of the n subsets contain between them at least k distinct elements.

Hall's and König's theorems

For example, the sets $S_1=(1, 2, 2)$, $S_2=(1, 2, 4)$, $S_3=(1, 2, 5)$, $S_4=(3, 4, 5, 6)$, $S_5=(3, 4, 5, 6)$ satisfy the conditions of the theorem, and a set of distinct representatives is $x_1=1$, $x_2=2$, $x_3=5$, $x_4=3$, $x_5=4$. On the other hand, the sets $T_1=(1, 2)$, $T_2=(1, 3)$, $T_3=(1, 4)$, $T_4=(2, 3)$, $T_5=(2, 4)$, $T_6=(1, 2, 5)$ do not possess a system of distinct representatives because T_1, T_2, T_3, T_4, T_5 possess between them only four elements.

The following theorem due to König is closely related to Hall's theorem and can be easily deduced from it. Conversely, Hall's theorem can be deduced from König's: If the elements of rectangular matrix are 0s and 1s, the minimum number of lines that contain all of the 1s is equal to the maximum number of 1s that can be chosen with no two on a line.

Ramsey's numbers. If $X=\{1, 2, \ldots, n\}$, and if T, the family of all subsets of X containing exactly r distinct elements, is divided into two mutually exclusive families α and β, the following conclusion that was originally obtained by the British mathematician Frank Plumpton Ramsey follows. He proved that for $r \geq 1$, $p \geq r$, $q \geq r$, there exists a number $N_r(p, q)$ depending solely on p, q, r, such that if $n > N_r(p, q)$, there is either a subset A of p elements all of the r subsets of which are in the family α or there is a subset B of q elements all of the r subsets of which are in the family β.

The set X can be a set of n persons. For $r=2$, T is the family of all pairs. If two persons have met each other the pair can belong to the family α. If two persons have not met, the pair can belong to the family β. If these things are assumed, then by Ramsey's theorem, for any given $p \geq 2$, $q \geq 2$ there exists a number $N_2(p, q)$, such that if $n > N_2(p, q)$, then among n persons invited to a party there will be either a set of p persons all of whom have met each other or a set of q persons no two of whom have met.

Although the existence of $N_r(p, q)$ is known, actual values are known only for a few cases. Because $N_r(p, q)=N_r(q, p)$, it is possible to take $p \leq q$. It is known that $N_2(3, 3)=6$, $N_2(3, 4)=9$, $N_2(3, 5)=14$, $N_2(3, 6)=18$, $N_2(4, 4)=18$. Some bounds are also known, for example, $25 \leq N_2(4, 5) \leq 28$.

A consequence of Ramsey's theorem is the following result obtained in 1935 by the Hungarian mathematicians Paul Erdös and George Szekeres. For a given integer n there exists an integer $N=N(n)$, such that a set of any N points on a plane, no three on a line, contains n points forming a convex n-gon.

DESIGNS, LATIN SQUARES, ARRAYS, AND CODING

BIB (balanced incomplete block) designs. A design is a set of $T=\{1, 2, \ldots, \upsilon\}$ objects called treatments and a family of subsets $B_1, B_2, \ldots, B_b$ of T, called blocks, such that the block B_i contains exactly k_i treatments, all distinct. The number k_i is called the size of the block B_i, and the ith treatment is said to be replicated r_i times if it occurs in exactly r_i blocks. Specific designs are subject to further constraints. The name design comes from statistical theory in which designs are used to estimate effects of treatments applied to experimental units.

A BIB design is a design with υ treatments and b blocks in which each block is of size k, each treatment is replicated r times, and every pair of distinct treatments occurs together in λ blocks. The design is said to have the parameters

$(\upsilon, b, r, k, \lambda)$. Some basic relations are easy to establish (see 20). These conditions are necessary but not sufficient for the existence of the design. The design is said to be proper if $k < \upsilon$—that is, the blocks are incomplete. For a proper BIB design Fisher's inequality $b \geq \upsilon$, or equivalently $r \geq k$, holds.

BIB design symmetry

A BIB design is said to be symmetric if $\upsilon = b$, and consequently $r = k$. Such a design is called a symmetric (υ, k, λ) design, and $\lambda(\upsilon - 1) = k(k-1)$. A necessary condition for the existence of a symmetric (υ, k, λ) design is given by the following:

A. If υ is even, $k - \lambda$ is a perfect square.

B. If υ is odd, a certain Diophantine equation (see 21) has a solution in integers not all zero.

For example, the designs $(\upsilon, k, \lambda) = (22, 7, 2)$ and $(46, 10, 2)$ are ruled out by (A) and the design $(29, 8, 2)$ by (B).

Because necessary and sufficient conditions for the existence of a BIB design with given parameters are not known, it is often a very difficult problem to decide whether a design with given parameters (satisfying the known necessary conditions) really exists. By 1972 there were only two unsettled cases with $r \leq 10$. These are $(\upsilon, b, r, k, \lambda) = (46, 69, 9, 6, 1)$ and $(51, 85, 10, 6, 1)$.

Methods of constructing BIB designs depend on the use of finite fields, finite geometries, and number theory. Some general methods were given in 1939 by the Indian mathematician Raj Chandra Bose, who has since emigrated to the United States.

A finite field is a finite set of marks with two operations, addition and multiplication, subject to the usual nine laws of addition and multiplication obeyed by rational numbers. In particular the marks may be taken to be the set X of non-negative integers less than a prime p. If this is so, then addition and multiplication are defined by modified addition and multiplication laws (see 22) in which $a, b, r,$ and p belong to X. For example, if $p = 7$, then $5 + 4 = 2$, $5 \cdot 4 = 6$. There exist more general finite fields in which the number of elements is p^n, p a prime. There is essentially one field with p^n elements, with given p and n. It is denoted by $GF(p^n)$.

Finite geometries can be obtained from finite fields in which the coordinates of points are now elements of a finite field.

A set of $k+1$ non-negative integers $d_0, d_1, \cdots, d_k$ is said to form a perfect difference set mod υ, if among the $k(k-1)$ differences $d_i - d_j$, $i \neq j$, $i, j = 0, 1, \cdots, k$, reduced mod υ, each nonzero positive integer less than υ occurs exactly the same number of times λ. For example, 1, 4, 5, 9, 3 is a difference set mod 11, with $\lambda = 2$. From a perfect difference set can be obtained the symmetric (υ, k, λ) design using the integers $0, 1, 2, \cdots, \upsilon - 1$. The jth block contains the treatments obtained by reducing mod υ the numbers $d_0 + j, d_1 + j, \cdots, d_i + j, j = 0, 1, \cdots, \upsilon - 1$.

It can be shown that any two blocks of a symmetric (υ, k, λ) design intersect in exactly k treatments. By deleting one block and all the treatments contained in it, it is possible to obtain from the symmetric design its residual, which is a BIB design (unsymmetric) with parameters $\upsilon^* = \upsilon - k$, $b^* = \upsilon - 1$, $r^* = k$, $k^* = k - \lambda$, $\lambda^* = \lambda$. One may ask whether it is true that a BIB design with the parameters of a residual can be embedded in a symmetric BIB design. The truth of this is rather easy to demonstrate when $\lambda = 1$. Hall and W.S. Connor in 1953 showed that it is also true for $\lambda = 2$. The Indian mathematician K.N. Bhattacharya in 1944, however, gave a counterexample for $\lambda = 3$ by exhibiting a BIB design with parameters $\upsilon = 16$, $b = 24$, $r = 9$, $k = 6$, $\lambda = 3$ for which two particular blocks intersect in four treatments and which for that reason cannot be embedded in a symmetric BIB design.

A BIB design is said to be resolvable if the set of blocks can be partitioned into subsets, such that the blocks in any subset contain every treatment exactly once. For the case $k = 3$ this problem was first posed during the 19th century by the British mathematician T.P. Kirkman as a recreational problem. There are υ girls in a class. Their teacher wants to take the class out for a walk for a number of days, the girls marching abreast in triplets. It is required to arrange the walk so that any two girls march abreast in the same triplet exactly once. It is easily shown that this is equivalent to the construction of a resolvable BIB design with $\upsilon = 6t + 3$, $b = (2t+1)(3t+1)$, $r = 3t + 1$, $k = 3$, $\lambda = 1$. Solutions were known for only a large number of special values of t until a completely general solution was finally given by the Indian and U.S. mathematicians Dwijendra K. Ray-Chaudhuri and R.M. Wilson in 1970.

PBIB (partially balanced incomplete block) designs. Given υ objects $1, 2, \cdots, \upsilon$, a relation satisfying the following conditions is said to be an m-class partially balanced association scheme:

Conditions for PBIB designs

A. Any two objects are either 1st, or 2nd, $\cdots$, or mth associates, the relation of association being symmetrical.

B. Each object α has n_i ith associates, the number n_i being independent of α.

C. If any two objects α and β are ith associates, then the number of objects that are jth associates of α and kth associates of β is $p_{jk}^{\,i}$ and is independent of the pair of ith associates α and β.

The constants υ, n_i, $p_{jk}^{\,i}$ are the parameters of the association scheme. A number of identities connecting these parameters were given by the Indian mathematicians Bose and K.R. Nair in 1939, but Bose and the U.S. mathematician D.M. Mesner in 1959 discovered new identities when $m > 2$.

A PBIB design is obtained by identifying the υ treatments with the υ objects of an association scheme and arranging them into b blocks satisfying the following conditions:

A. Each contains k treatments.

B. Each treatment occurs in r blocks.

C. If two treatments are ith associates, they occur together in λ_i blocks.

Two-class association schemes and the corresponding designs are especially important both from the mathematical point of view and because of statistical applications. For a two-class association scheme the constancy of υ, n_i, $p_{11}^{\,1}$, and $p_{11}^{\,2}$ ensures the constancy of the other parameters. Seven relations hold (see 23). Sufficient conditions for the existence of association schemes with given parameters are not known, but for a two-class association scheme Connor and the U.S. mathematician Willard H. Clatworthy in 1954 obtained some necessary conditions (see 24).

$$(19)\quad \begin{cases} \text{If} & f(A) = \sum_{S \subset A} g(S), \\ \text{then} & g(A) = \sum_{S \subset A} (-1)^{|A|-|S|} f(S). \end{cases}$$

$$(20)\quad bk = vr, \qquad \lambda(v-1) = r(k-1)$$

$$(21)\quad x^2 = (k-\lambda)y^2 + (-1)^{(v-1)/2}\lambda z^2$$

$$(22)\quad a + b = s \pmod{p}, \qquad ab = c \pmod{p}$$

$$(23)\quad \begin{cases} p_{12}^1 = n_1 - p_{11}^1 - 1 = p_{21}^1, \qquad p_{22}^1 = n_2 - n_1 + p_{11}^1 + 1 \\ p_{12}^2 = n_1 - p_{11}^2 = p_{21}^2, \qquad p_{22}^2 = n_2 - n_1 + p_{11}^2 \\ v = n_1 + n_2 + 1, \qquad n_1 p_{12}^1 = n_2 p_{11}^2, \qquad n_1 p_{22}^1 = n_2 p_{12}^2 \end{cases}$$

$$(24)\quad \begin{cases} \alpha_1, \alpha_2 = \dfrac{n_1 + n_2}{2} \pm \dfrac{(n_1 - n_2) + \gamma(n_1 + n_2)}{2\sqrt{\Delta}} \\ \text{These numbers must be non-negative integers, in which} \\ \gamma = p_{12}^2 - p_{12}^1, \qquad \Delta = (p_{12}^2 - p_{12}^1)^2 + 2(p_{12}^2 + p_{12}^1) + 1. \end{cases}$$

$$(25)\quad \text{If } k = p_1^{n_1} p_2^{n_2} \cdots p_u^{n_u},\ n(k) = \min(p_1^{n_1}, p_2^{n_2}, \cdots, p_u^{n_u})$$

Orthogonal Latin squares. A Latin square of order k is defined as a $k \times k$ square grid, the k^2 cells of which are occupied by k distinct symbols of a set $X = 1, 2, \ldots, k$, such that each symbol occurs once in each row and each column. Two Latin squares are said to be orthogonal if, when superposed, any symbol of the first square occurs exactly once with each symbol of the second square.

Two orthogonal Latin squares of order 4 are exhibited in Figure 2.

A set of mutually orthogonal Latin squares is a set of Latin squares any two of which are orthogonal. It is easily shown that there cannot exist more than $k-1$ mutually orthogonal Latin squares of a given order k. When $k-1$ mutually orthogonal Latin squares of order k exist, the set is complete. A complete set always exists if k is the power of a prime. An unsolved question is whether there can exist a complete set of mutually orthogonal Latin squares of order k if k is not a prime power.

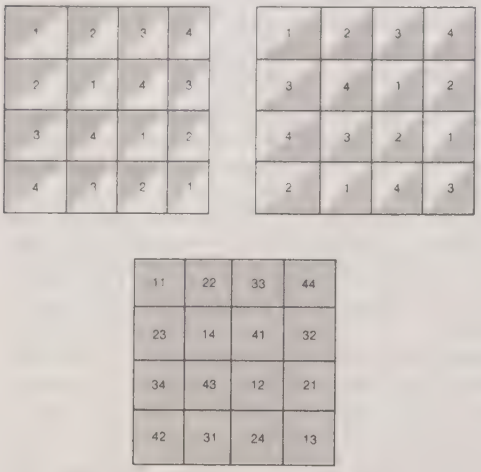

Figure 2: Two orthogonal Latin squares of order 4 and their superposition.

Many types of experimental designs are based on Latin squares. Hence, the construction of mutually orthogonal Latin squares is an important combinatorial problem. Letting the prime power decomposition of an integer k be given, the arithmetic function $n(k)$ is defined by taking the minimum of the factors in such a decomposition (see 25).

Letting $N(k)$ denote the maximum number of mutually orthogonal Latin squares of order k, the U.S. mathematician H.F. MacNeish in 1922 showed that there always exist $n(k)$ mutually orthogonal Latin squares of order k and conjectured that this is the maximum number of such squares—that is, $N(k)=n(k)$. There was also the long-standing conjecture of Euler, formulated in 1782, that there cannot exist mutually orthogonal Latin squares of order $4t+2$, for any integer t. MacNeish's conjecture, if true, would imply the truth of Euler's but not conversely. The U.S. mathematician E.T. Parker in 1958 disproved the conjecture of MacNeish. This left open the question of Euler's conjecture. Bose and the Indian mathematician S.S. Shrikhande in 1959–60 obtained the first counterexample to Euler's conjecture by obtaining two mutually orthogonal Latin squares of order 22 and then generalized their method to disprove Euler's conjecture for an infinity of values of $k=2(\text{mod } 4)$. Parker in 1959 used the method of differences to show the falsity of Euler's conjecture for all $k=(3q+1)/2$, in which q is a prime power, $q\equiv 3(\text{mod } 4)$. Finally these three mathematicians in 1960 showed that $N(k)\geq 2$ whenever $k>6$. It is pertinent to inquire about the behaviour of $N(k)$ for large k. The best result in this direction is due to R.M. Wilson in 1971. He shows that $N(k)\geq k^{1/17}-2$ for large k.

Euler's conjecture

Orthogonal arrays and the packing problem. A $k\times N$ matrix A with entries from a set X of $s\geq 2$ symbols is called an orthogonal array of strength t, size N, k constraints, and s levels if each $t\times N$ submatrix of A contains all possible $t\times 1$ column vectors with the same frequency λ. The array may be denoted by (N, k, s, t). The number λ is called the index of the array, and $N=\lambda s^t$. This concept is due to the Indian mathematician C.R. Rao and was obtained in 1947.

Orthogonal arrays are a generalization of orthogonal Latin squares. Indeed, the existence of an orthogonal array of k constraints, s levels, strength 2, and index unity is combinatorially equivalent to the existence of a set of $k-2$ mutually orthogonal Latin squares of order s. For a given λ, s, and t it is an important combinatorial problem to obtain an orthogonal array (N, k, s, t), $N=s^t$, for which the number of constraints k is maximal.

Orthogonal arrays play an important part in the theory of factorial designs in which each treatment is a combination of factors at different levels. For an orthogonal array $(\lambda s^t, k, s, t)$, $t\geq 2$, the number of constraints k satisfies an inequality (see 26) in which λs^t is greater than or equal to a linear expression in powers of $(s-1)$, with binomial coefficients giving the number of combinations of $k-1$ or k things taken i at a time $(i\leq u)$.

Letting $GF(q)$ be a finite field with $q=p^h$ elements, an $n\times r$ matrix with elements from the field is said to have the property P_t if any t rows are independent. The problem is to construct for any given r a matrix H with the maximum number of rows possessing the property P_t. The maximal number of rows is denoted by $n_t(r, q)$. This packing problem is of great importance in the theory of factorial designs and also in communication theory, because the existence of an $n\times r$ matrix with the property P_t leads to the construction of an orthogonal array (q^r, n, q, t) of index unity.

Again $n\times r$ matrices H with the property P_t may be used in the construction of error-correcting codes. A row vector c' is taken as a code word if and only if $c'H=0$. The code words then are of length n and differ in at least $t+1$ places. If $t=2u$, then u or fewer errors of transmission can be corrected if such a code is used. If $t=2u+1$, then an additional error can be detected.

A general solution of the packing problem is known only for the case $t=2$, the corresponding codes being the one-error-correcting codes of the U.S. mathematician Richard W. Hamming. When $t=3$ the solution is known for general r when $q=2$ and for general q when $r\leq 4$. Thus, $n_2(r, 2)=(q^r-1)/(q-1)$, $n_3(r, 2)=2^{r-1}$, $n_3(3, q)=q+1$ or $q+2$, according as q is odd or even. If $q>2$, then $n_3(4, q)=q^2+1$. The case $q=2$ is especially important because in practice most codes use only two symbols, 0 or 1. Only fairly large values of r are useful, say, $r\geq 25$. The optimum value of $n_t(r, 2)$ is not known. The BCH codes obtained by Bose and Ray-Chaudhuri and independently by the French mathematician Alexis Hocquenghem in 1959 and 1960 are based on a construction that yields an $n\times r$ matrix H with the property P_{2u} in which $r\leq mu$, $n=2^m-1$, $q=2$. They can correct up to u errors.

BCH codes

GRAPH THEORY

Definitions. A graph G consists of a non-empty set of elements $V(G)$ and a subset $E(G)$ of the set of unordered pairs of distinct elements of $V(G)$. The elements of $V(G)$, called vertices of G, may be represented by points. If $(x, y)\in E(G)$, then the edge (x, y) may be represented by an arc joining x and y. Then x and y are said to be adjacent, and the edge (x, y) is incident with x and y. If (x, y) is not an edge, then the vertices x and y are said to be nonadjacent. G is a finite graph if $V(G)$ is finite. A graph H is a subgraph of G if $V(H)\subset V(G)$ and $E(H)\subset E(G)$.

A chain of a graph G is an alternating sequence of vertices and edges $x_0, e_1, x_1, e_2, \cdots e_n, x_n$, beginning and ending with vertices in which each edge is incident with the two vertices immediately preceding and following it. This chain joins x_0 and x_n and may also be denoted by $x_0, x_1, \cdots, x_n$, the edges being evident by context. The chain is closed if $x_0=x_n$, and open otherwise. If the chain is closed, it is called a cycle, provided its vertices (other than x_0 and x_n) are distinct and $n\geq 3$. The length of a chain is the number of edges in it.

A graph G is labelled when the various υ vertices are distinguished by such names as $x_1, x_2, \cdots x_\upsilon$. Two graphs G and H are said to be isomorphic (written $G\simeq H$) if there exists a one–one correspondence between their vertex sets that preserves adjacency. For example, G_1 and G_2, shown in Figure 3, are isomorphic under the correspondence $x_i\leftrightarrow y_i$.

Two isomorphic graphs count as the same (unlabelled) graph. A graph is said to be a tree if it contains no cycle—for example, the graph G_3 of Figure 3.

Enumeration of graphs. The number of labelled graphs with υ vertices is $2^{\upsilon(\upsilon-1)/2}$ because $\upsilon(\upsilon-1)/2$ is the number

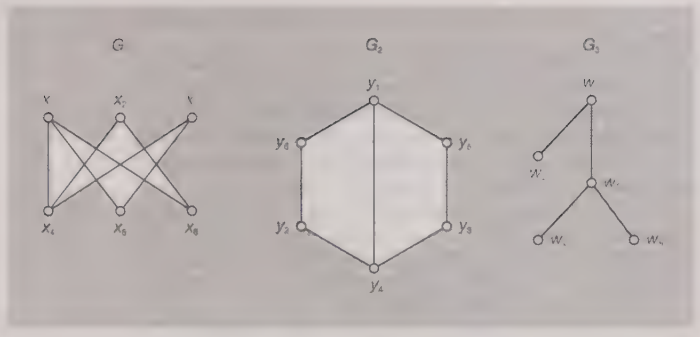

Figure 3: Two isomorphic graphs and a tree.

of pairs of vertices, and each pair is either an edge or not an edge. Cayley in 1889 showed that the number of labelled trees with υ vertices is $\upsilon^{\upsilon-2}$.

The number of unlabelled graphs with υ vertices can be obtained by using Polya's theorem. The first few terms of the generating function $F(x)$, in which the coefficient of x^{υ} gives the number of (unlabelled) graphs with υ vertices, can be given (see 27).

A rooted tree has one point, its root, distinguished from others. If T_{υ} is the number of rooted trees with υ vertices, the generating function for T_{υ} can also be given (see 28).

Polya in 1937 showed in his memoir already referred to that the generating function for rooted trees satisfies a functional equation (see 29). Letting t_{υ} be the number of (unlabelled) trees with υ vertices, the generating function $t(x)$ for t_{υ} can be obtained in terms of $T(x)$ (see 30). This result was obtained in 1948 by the American mathematician Richard R. Otter.

Many enumeration problems on graphs with specified properties can be solved by the application of Polya's theorem and a generalization of it made by a Dutch mathematician, N.G. de Bruijn, in 1959.

Characterization problems of graph theory. If there is a class C of graphs each of which possesses a certain set of properties P, then the set of properties P is said to characterize the class C, provided every graph G possessing the properties P belongs to the class C. Sometimes it happens that there are some exceptional graphs that possess the properties P. Many such characterizations are known. Here is presented a typical example.

A complete graph K_m is a graph with m vertices, any two of which are adjacent. The line graph H of a graph G is a graph the vertices of which correspond to the edges of G, any two vertices of H being adjacent if and only if the corresponding edges of G are incident with the same vertex of G.

A graph G is said to be regular of degree n_1 if each vertex is adjacent to exactly n_1 other vertices. A regular graph of degree n_1 with υ vertices is said to be strongly regular with parameters $(\upsilon, n_1, p_{11}^1, p_{11}^2)$ if any two adjacent vertices are both adjacent to exactly p_{11}^1 other vertices and any two nonadjacent vertices are both adjacent to exactly p_{11}^2 other vertices. A strongly regular graph and a two-class association are isomorphic concepts. The treatments of the scheme correspond to the vertices of the graph, two treatments being either first associates or second associates according as the corresponding vertices are either adjacent or nonadjacent.

It is easily proved that the line graph $T_2(m)$ of a complete graph K_m, $m \geq 4$ is strongly regular with parameters $\upsilon = m(m-1)/2$, $n_1 = 2(m-2)$, $p_{11}^1 = m-2$, $p_{11}^2 = 4$.

It is surprising that these properties characterize $T_2(m)$ except for $m = 8$, in which case there exist three other strongly regular graphs with the same parameters nonisomorphic to each other and to $T_2(m)$.

Partial geometries

A partial geometry (r, k, t) is a system of two kinds of objects, points and lines, with an incidence relation obeying the following axioms:

1. Any two points are incident with not more than one line.
2. Each point is incident with r lines.
3. Each line is incident with k points.
4. Given a point P not incident with a line ℓ, there are exactly t lines incident with P and also with some point of ℓ.

A graph G is obtained from a partial geometry by taking the points of the geometry as vertices of G, two vertices of G being adjacent if and only if the corresponding points are incident with the same line of the geometry. It is strongly regular with parameters

$$\upsilon = k[(r-1)(k-1)+t]/t,\ n_1 = r(k-1),$$
$$p_{11}^1 = (r-1)(t-1)+(k-2),\ p_{11}^2 = rt.$$

The question of whether a strongly regular graph with the above parameters is the graph of some partial geometry is of interest. It was shown by Bose in 1963 that the answer is in the affirmative if a certain condition holds (see 31). Not much is known about the case if this condition is not satisfied, except for certain values of r and t. For example, $T_2(m)$ is isomorphic with the graph of a partial geometry $(2, m-1, 2)$. Hence, for $m > 8$ its characterization is a consequence of the above theorem. Another consequence is the following:

Given a set of k-1-d mutually orthogonal Latin squares of order k, the set can be extended to a complete set of k-1 mutually orthogonal squares if a condition holds (see 32). The case $d = 2$ is due to Shrikhande in 1961 and the general result to the American mathematician Richard H. Bruck in 1963.

Planar graphs. A graph G is said to be planar if it can be represented on a plane in such a fashion that the vertices are all distinct points, the edges are simple curves, and no two edges meet one another except at their terminals. For example, K_4, the complete graph on four vertices, is planar, as Figure 4A shows.

Two graphs are said to be homeomorphic if both can be obtained from the same graph by subdivisions of edges. For example, the graphs in Figure 4A and Figure 4B are homeomorphic.

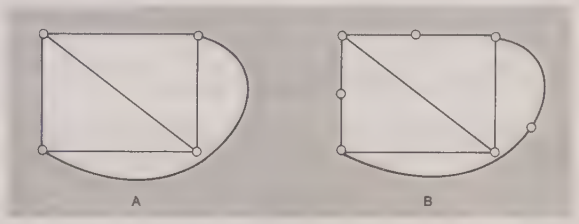

Figure 4: Two homeomorphic graphs A and B.

The $K_{m,n}$ graph is a graph for which the vertex set can be divided into two subsets, one with m vertices and the other with n vertices. Any two vertices of the same subset are nonadjacent, whereas any two vertices of different subsets are adjacent. The Polish mathematician Kazimierz Kuratowski in 1930 proved the following famous theorem:

A necessary and sufficient condition for a graph G to be planar is that it does not contain a subgraph homeomorphic to either K_5 or $K_{3,3}$ shown in Figure 5.

An elementary contraction of a graph G is a transformation of G to a new graph G_1, such that two adjacent vertices u and υ of G are replaced by a new vertex w in G_1 and w is adjacent in G_1 to all vertices to which either u or υ is adjacent in G. A graph G^* is said to be a contraction of G if G^* can be obtained from G by a sequence of elementary contractions. The following is another characterization of a planar graph due to the German mathematician K. Wagner in 1937.

A graph is planar if and only if it is not contractible to K_5 or $K_{3,3}$.

The four-colour map problem. For more than a century the solution of the four-colour map problem eluded every analyst who attempted it. The problem may have attracted the attention of Möbius, but the first written reference to it seems to be a letter from one Francis Guthrie to his brother, a student of Augustus De Morgan, in 1852.

The problem concerns planar maps—that is, subdivisions of the plane into nonoverlapping regions bounded by simple closed curves. In geographical maps it has been observed empirically, in as many special cases as have

$$\lambda s^t \geq 1 + \binom{k}{1}(s-1) + \cdots + \binom{k}{u}(s-1)^u, \quad \text{if } t = 2u \tag{26}$$

$$\lambda s^t \geq 1 + \binom{k}{1}(s-1) + \cdots + \binom{k}{u}(s-1)^u + \binom{k-1}{u}(s-1)^{u+1}, \quad \text{if } t = 2u+1.$$

$$F(x) = 1 + x + 2x^2 + 4x^3 + 11x^4 + 34x^5 + 156x^6 + \tag{27}$$
$$+ 1{,}044x^7 + 12{,}346x^8 + 308{,}708x^9 + \cdots$$

$$T(x) = \sum_{r=1}^{\infty} T_r x^r = x \prod_{r=1}^{\infty} (1 - x^r)^{-T_r} \tag{28}$$

$$T(x) = x \exp \sum_{r=1}^{\infty} \frac{1}{r} T(x^r) \tag{29}$$

$$t(x) = T(x) - \tfrac{1}{2}[T^2(x) - T(x^2)] \tag{30}$$

$$k > \tfrac{1}{2}[r(r-1) + t(r+1)(r^2 - 2r + 2)] \tag{31}$$

$$k > \tfrac{1}{2}(d-1)(d^3 - d^2 + d + 2) \tag{32}$$

been tried, that, at most, four colours are needed in order to colour the regions so that two regions that share a common boundary are always coloured differently, and in certain cases that at least four colours are necessary. (Regions that meet only at a point, such as the states of Colorado and Arizona in the United States, are not considered to have a common boundary). A formalization of this empirical observation constitutes what is called "the four-colour theorem." The problem is to prove or disprove the assertion that this is the case for every planar map. That three colours will not suffice is easily demonstrated, whereas the sufficiency of five colours was proved in 1890 by the British mathematician P.J. Heawood.

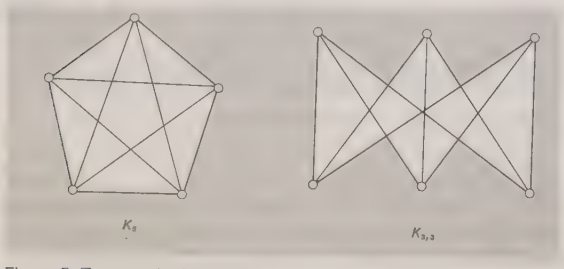

Figure 5: Two graphs important to planar properties.

In 1879 A.B. Kempe, an Englishman, proposed a solution of the four-colour problem. Although Heawood showed that Kempe's argument was flawed, two of its concepts proved fruitful in later investigation. One of these, called unavoidability, correctly states the impossibility of constructing a map in which every one of four configurations is absent (these configurations consist of a region with two neighbours, one with three, one with four, and one with five). The second concept, that of reducibility, takes its name from Kempe's valid proof that if there is a map that requires at least five colours and that contains a region with four (or three or two) neighbours, then there must be a map requiring five colours for a smaller number of regions. Kempe's attempt to prove the reducibility of a map containing a region with five neighbours was erroneous, but it was rectified in a proof published in 1976 by Kenneth Appel and Wolfgang Haken of the United States. Their proof attracted some criticism because it necessitated the evaluation of 1,936 distinct cases, each involving as many as 500,000 logical operations. Appel, Haken, and their collaborators devised programs that made it possible for a large digital computer to handle these details. The computer required more than 1,000 hours to perform the task, and the resulting formal proof is several hundred pages long.

Eulerian cycles and the Königsberg bridge problem. A multigraph G consists of a non-empty set $V(G)$ of vertices and a subset $E(G)$ of the set of unordered pairs of distinct elements of $V(G)$ with a frequency $f \geq 1$ attached to each pair. If the pair (x_1, x_2) with frequency f belongs to $E(G)$, then vertices x_1 and x_2 are joined by f edges.

An Eulerian cycle of a multigraph G is a closed chain in which each edge appears exactly once. Euler showed that a multigraph possesses an Eulerian cycle if and only if it is connected (apart from isolated points) and the number of vertices of odd degree is either zero or two.

This problem first arose in the following manner. The Pregel River, formed by the confluence of its two branches, runs through the town of Königsberg and flows on either side of the island of Kneiphof. There were seven bridges, as shown in Figure 6A. The townspeople wondered whether it was possible to go for a walk and cross each bridge once and once only. This is equivalent to finding an Eulerian cycle for the multigraph in Figure 6B. Euler showed it to be impossible because there are four vertices of odd order.

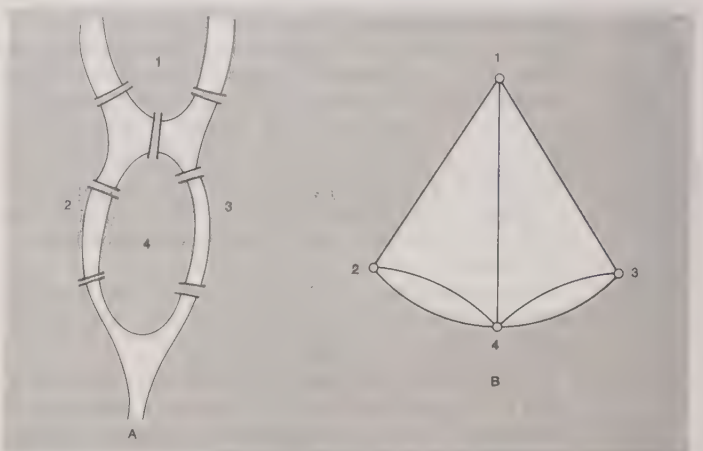

Figure 6: (A) Seven bridges of Königsberg and (B) multigraph.

Directed graphs. A directed graph G consists of a non-empty set of elements $V(G)$, called vertices, and a subset $E(G)$ of ordered pairs of distinct elements of $V(G)$. Elements (x, y) of $E(G)$ may be called edges, the direction of the edge being from x to y. Both (x, y) and (y, x) may be edges.

A closed path in a directed graph is a sequence of vertices $x_0x_1x_2 \cdots x_n = x_0$, such that (x_i, x_{i+1}) is a directed edge for $i = 0, 1, \cdots, n-1$. To each edge (x, y) of a directed graph G there can be assigned a non-negative weight function $f(x, y)$. The problem then is to find a closed path in G traversing all vertices so that the sum of the weights of all edges in the path is a minimum. This is a typical optimization problem. If the vertices are certain cities, the edges are routes joining cities, and the weights are the lengths of the routes, then this becomes the travelling-salesman problem—that is, can he visit each city without retracing his steps? This problem still remains unsolved except for certain special cases. (R.C.Bo./Ed.)

Combinatorial geometry

The name combinatorial geometry, first used by Hadwiger, is not quite accurately descriptive of the nature of the subject. Combinatorial geometry does touch on those aspects of geometry that deal with arrangements, combinations, and enumerations of geometric objects; but it takes in much more. The field is so new that there has scarcely been time for it to acquire a well-defined position in the mathematical world. Rather it tends to overlap parts of topology (especially algebraic topology), number theory, analysis, and, of course, geometry. The subject concerns itself with relations among members of finite systems of geometric figures subject to various conditions and restrictions. More specifically, it includes problems of

Principal concerns

covering, packing, symmetry, extrema (maxima and minima), continuity, tangency, equalities, and inequalities, many of these with special emphasis on their application to the theory of convex bodies. A few of the fundamental problems of combinatorial geometry originated with Newton and Euler; the majority of the significant advances in the field, however, have been made since 1946.

The unifying aspect of these disparate topics is the quality or style or spirit of the questions and the methods of attacking these questions. Among those branches of mathematics that interest serious working mathematicians, combinatorial geometry is one of the few branches that can be presented on an intuitive basis, without recourse by the investigator to any advanced theoretical considerations or abstractions.

Yet the problems are far from trivial, and many remain unsolved. They can be handled only with the aid of the most careful and often delicate reasoning that displays the variety and vitality of geometric methods in a modern setting. A few of the answers are natural and are intuitively suggested by the questions. Many of the others, however, require proofs of unusual ingenuity and depth even in the two-dimensional case. Sometimes a plane solution may be readily extendible to higher dimensions, but sometimes just the opposite is true, and a three-dimensional or n-dimensional problem may be entirely different from its two-dimensional counterpart. Each new problem must be attacked individually. Attempts to create standard methods or theories capable of being applied to the solution of any significant group of the currently unsolved problems in the field had by the late 20th century met with no success. The continuing charm and challenge of the subject are at least in part due to the relative simplicity of the statements coupled with the elusive nature of their solutions.

SOME HISTORICALLY IMPORTANT TOPICS OF COMBINATORIAL GEOMETRY

Packing and covering. It is easily seen that six equal circular disks may be placed around another disk of the same size so that the central one is touched by all the others but no two overlap (Figure 7) and that it is not possible to place seven disks in such a way. In the analogous three-dimensional situation, around a given ball (solid sphere) it is possible to place 12 balls of equal size, all touching the first one but not overlapping it or each other. One such arrangement may be obtained by placing the 12 surrounding balls at the midpoints of edges of a suitable cube that encloses the central ball; each of the 12 balls then touches four other balls in addition to the central one. But if the 12 balls are centred at the 12 vertices of a suitable regular icosahedron surrounding the given ball, there is an appreciable amount of free space between each of the surrounding balls and its neighbours. (If the spheres have radius 1, the distances between the centres of the surrounding spheres are at least $2/\cos 18° = 2.1029 \cdots$.) It appears, therefore, that by judicious positioning it might be possible to have 13 equal non-overlapping spheres touch another of the same size. This dilemma between 12 and 13, one of the first nontrivial problems of combinatorial geometry, was the object of discussion between Isaac Newton and David Gregory in 1694. Newton believed 12 to be the correct number, but this claim was not proved until 1874. The analogous problem in four-dimensional space is still open, the answer being one of the numbers 24, 25, or 26.

Problem of the 13 balls

The problem of the 13 balls is a typical example of the branch of combinatorial geometry that deals with packings and coverings. In packing problems the aim is to place figures of a given shape or size without overlap as economically as possibly, either inside another given figure or subject to some other restriction.

Problems of packing and covering have been the objects of much study, and some striking conclusions have been obtained. For each plane convex set K, for example, it is possible to arrange nonoverlapping translates of K so as to cover at least two-thirds of the plane; if K is a triangle (and only in that case), no arrangement of nonoverlapping translates covers more than two-thirds of the plane (Figure 8). On the other hand, many easily stated questions are still open. One of them concerns the densest packing of spheres. If the spheres are packed in cannonball fashion—that is, in the way cannonballs are stacked to form a triangular pyramid, indefinitely extended—then they fill $\pi/\sqrt{18}$, or about 0.74, of the space. Whether this is the greatest density possible is not known, but it was proved in 1958 by the British mathematician C. Ambrose Rogers that, if there exists a closer packing, its density cannot exceed 0.78.

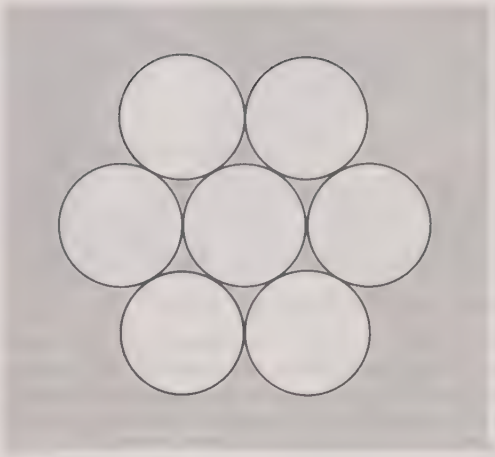

Figure 7: Packing of disks.

Covering problems deal in an analogous manner with economical ways of placing given figures so as to cover (that is, contain in their union) another given figure. One famous covering problem, posed by the French mathematician Henri Lebesgue in 1914, is still unsolved: What is the size and shape of the universal cover of least area? Here a convex set C is called universal cover if for each set A in the plane such that diam $A \leq 1$ it is possible to move C to a suitable position in which it covers A. The diameter diam A of a set A is defined as the least upper bound of the mutual distances of points of the set A. If A is a compact set, then diam A is simply the greatest distance between any two points of A. Thus, if A is an equilateral triangle of side 1, then diam $A = 1$; and if B is a cube of edge length 1, then diam $B = \sqrt{3}$.

The Lebesgue problem

Polytopes. A (convex) polytope is the convex hull of some finite set of points (see GEOMETRY: *Euclidean geometry*). Each polytope of dimensions d has as faces finitely many polytopes of dimensions 0 (vertices), 1 (edge), 2 (2-faces), $\cdots$, d-1 (facets). Two-dimensional polytopes are usually called polygons, three-dimensional ones polyhedra. Two polytopes are said to be isomorphic, or of the same combinatorial type, provided there exists a one-to-one correspondence between their faces, such that two faces of the first polytope meet if and only if the corresponding faces of the second meet. The prism and the

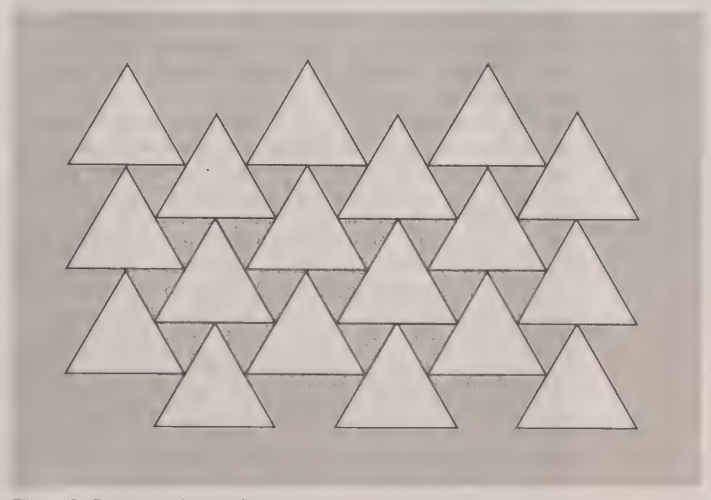

Figure 8: Covering of part of a plane with triangles.

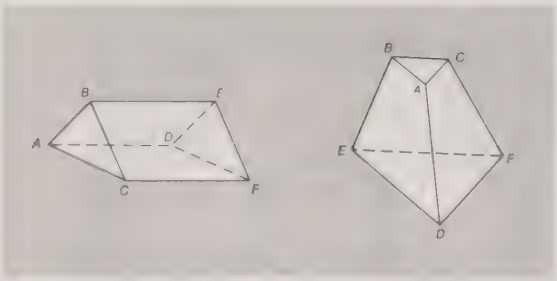

Figure 9: (Left) prism and (right) truncated pyramid.

truncated pyramid of Figure 9 are isomorphic, the correspondence being indicated by the letters at the vertices. To classify the convex polygons by their combinatorial types, it is sufficient to determine the number of vertices υ; for each $\upsilon \geq 3$, all polygons with υ vertices (υ-gons) are of the same combinatorial type, while a υ-gon and a υ'-gon are not isomorphic if $\upsilon \neq \upsilon'$. Euler was the first to investigate in 1752 the analogous question concerning polyhedra. He found that $\upsilon - e + f = 2$ for every convex polyhedron, where υ, e, and f are the numbers of vertices, edges, and faces of the polyhedron. Though this formula became one of the starting points of topology (see GEOMETRY: *Topology*), Euler was not successful in his attempts to find a classification scheme for convex polytopes or to determine the number of different types for each υ. Despite efforts of many famous mathematicians since Euler (J. Steiner, Kirkman, Cayley, O. Hermes, M. Brückner, to mention only a few from the 19th century), the problem is still open. It was established by P.J. Federico in the U.S. that there are 2,606 different combinatorial types of convex polyhedra with nine vertices. The numbers of different types with four, five, six, seven, or eight vertices have been known for some time to be 1, 2, 7, 34, and 257, respectively.

Theory of convex polytopes

The theory of convex polytopes has been more successful in developments in other directions. The regular polytopes have been under investigation since 1880 in dimensions higher than three, together with extensions of Euler's relation to the higher dimensions. (The Swiss geometer Ludwig Schläfli made many of these discoveries some 30 years earlier, but his work was published only posthumously in 1901.) The interest in regular polyhedra and other special polyhedra goes back to ancient Greece, as indicated by the names Platonic solids and Archimedean solids.

Since 1950 there has been considerable interest, in part created by practical problems related to computer techniques such as linear programming, in questions of the following type: for polytopes of a given dimension d and having a given number υ of vertices, how large and how small can the number of facets be? Such problems have provided great impetus to the development of the theory. The U.S. mathematician Victor L. Klee solved the maximum problem in 1963 in most cases (that is, for all but a finite number of υ's for each d), but the remaining cases were disposed of only in 1970 by P. McMullen, in the United States, who used a completely new method. The minimum problem and many related questions are still unsolved.

Incidence problems. In 1893 Sylvester posed the question: If a finite set S of points in a plane has the property that each line determined by two points of S meets at least one other point of S, must all points of S be on one line? Sylvester never found a satisfactory solution to the problem, and the first (affirmative) solutions were published a half century later. Since then, Sylvester's problem has inspired many investigations and led to many other open questions, both in the plane and in higher dimensions.

Helly's theorem. In 1912 E. Helly proved the following theorem, which has since found applications in many areas of geometry and analysis and has led to numerous generalizations, extensions and analogues known as Helly-type theorems. If $K_1, K_2, \cdots, K_n$ are convex sets in d-dimensional Euclidean space E^d, in which $n \geq d+1$, and if for every choice of $d+1$ of the sets K_i there exists a point that belongs to all the chosen sets, then there exists a point that belongs to all the sets $K_1, K_2, \cdots K_n$. The theorem stated in two dimensions is easier to visualize and yet is not shorn of its strength: If every three of a set of n convex figures in the plane have a common point (not necessarily the same point for all trios), then all n figures have a point in common. If, for example, convex sets A, B, and C have the point p in common, and convex sets A, B, and D have the point q in common, and sets A, C, and D have the point r in common, and sets B, C, and D have the point s in common, then some point x is a member of A, B, C, and D.

Although the connection is often far from obvious, many consequences may be derived from Helly's theorem. Among them are the following, stated for $d = 2$ with some higher dimensional analogues indicated in square brackets:

A. Two finite subsets X and Y of the plane [d-space] may be strictly separated by a suitable straight line [hyperplane] if and only if, for every set Z consisting of at most 4 [$d+2$] points taken from $X \cup Y$, the points of $X \cap Z$ may be strictly separated from those of $Y \cap Z$. (A line [hyperplane] L strictly separates X and Y if X is contained in one of the open half planes [half spaces] determined by L and if Y is contained in the other.)

B. Each compact convex set K in the plane [d-space] contains a point P with the following property: each chord of K that contains P is divided by P into a number of segments so the ratio of their lengths is at most $2d$.

C. If G is an open subset of the plane [d-space] with finite area [d-dimensional content], then there exists a point P, such that each open half plane [half space] that contains P contains also at least $1/3$ [$1/(d+1)$] of the area [d-content] of G.

D. If $I_1, \cdots, I_n$ are segments parallel to the y-axis in a plane with a coordinate system (x, y), and if for every choice of three of the segments there exists a straight line intersecting each of the three segments, then there exists a straight line that intersects all the segments $I_1, \cdots, I_n$.

Theorem D has generalizations in which kth degree polynomial curves $y = a_k x^k + \cdots + a_1 x + a_0$ take the place of the straight lines and $k+2$ replaces 3 in the assumptions. These are important in the theory of best approximation of functions by polynomials.

METHODS OF COMBINATORIAL GEOMETRY

Many other branches of combinatorial geometry are as important and interesting as those mentioned above, but rather than list them here it is more instructive to provide a few typical examples of frequently used methods of reasoning. Because the emphasis is on illustrating the methods rather than on obtaining the most general results, the examples will deal with problems in two and three dimensions.

Exhausting the possibilities. Using the data available concerning the problem under investigation, it is often possible to obtain a list of all potential, a priori possible, solutions. The final step then consists in eliminating the possibilities that are not actual solutions or that duplicate previously found solutions. An example is the proof that there are only five regular convex polyhedra (the Platonic solids) and the determination of what these five are.

The five Platonic solids

From the definition of regularity it is easy to deduce that all the faces of a Platonic solid must be congruent regular k-gons for a suitable k, and that all the vertices must belong to the same number j of k-gons. Because the sum of the face angles at a vertex of a convex polyhedron is less than 2π, and because each angle of the k-gon is $(k-2)\pi/k$, it follows that $j(k-2)\pi/k < 2\pi$, or $(j-2)(k-2) < 4$. Therefore, the only possibilities for the pair (j, k) are (3, 3), (3, 4), (3, 5), (4, 3), and (5, 3). It may be verified that each of these pairs actually corresponds to a Platonic solid, namely, to the tetrahedron, the cube, the dodecahedron, the octahedron, and the icosahedron, respectively. Very similar arguments may be used in the determination of Archimedean solids and in other instances.

The most serious drawback of the method is that in many instances the number of potential (and perhaps actual) solutions is so large as to render the method unfeasible. For example, it is known that the number of different combinatorial types of convex polyhedra with 10 vertices

exceeds 30,000, the number with 11 vertices exceeds 400,000, and the number with 12 vertices exceeds 5,000,000. Therefore, the exact determination of these numbers by the method just discussed is out of the question, certainly if attempted by hand and probably even with the aid of a computer.

Use of extremal properties. In many cases the existence of a figure or an arrangement with certain desired properties may be established by considering a more general problem (or a completely different problem) and by showing that a solution of the general problem that is extremal in some sense provides also a solution to the original problem. Frequently there seems to be very little connection between the initial question and the extremal problem. As an illustration the following theorem will be proved: If K is a two-dimensional compact convex set with a centre of symmetry, there exists a parallelogram P containing K, such that the midpoints of the sides of P belong to K. The proof proceeds as follows: Of all the parallelograms that contain K, the one with least possible area is labeled P_0. The existence of such a P_0 is a consequence of the compactness of K and may be established by standard arguments. It is also easily seen that the centres of K and P_0 coincide. The interesting aspect of the situation is that P_0 may be taken as the P required for the theorem. In fact (Figure 10), if the midpoints A' and A'' of a pair of sides of P_0 do not belong to K, it is possible to

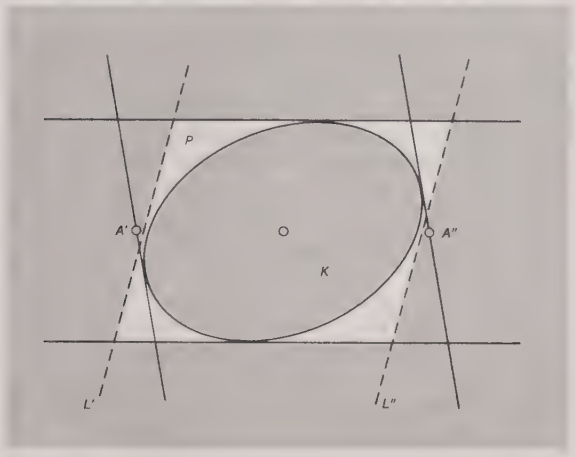

Figure 10: Example of theorem on extremal properties (see text).

strictly separate them from K by parallel lines L' and L'' that, together with the other pair of sides of P_0, determine a new parallelogram containing K but with area smaller than that of P_0. The above theorem and its proof generalize immediately to higher dimensions and lead to results that are important in functional analysis (see ANALYSIS [IN MATHEMATICS]: *Functional analysis*).

Disproof of existence of extremal figures

Sometimes this type of argument is used in reverse to establish the existence of certain objects by disproving the possibility of existence of some extremal figures. As an example the following solution of the problem of Sylvester discussed above can be mentioned. By a standard argument of projective geometry (duality), it is evident that Sylvester's problem is equivalent to the question: If through the point of intersection of any two of n coplanar lines, no two of which are parallel, there passes a third, are the n lines necessarily concurrent? To show that they must be concurrent, contradiction can be derived from the assumption that they are not concurrent. If L is one of the lines, then not all the intersection points lie on L. Among the intersection points not on L, there must be one nearest to L, which can be called A. Through A pass at least three lines, which meet L in points B, C, D, so that C is between B and D. Through C passes a line L^* different from L and from the line through A. Since L^* enters the triangle ABD, it intersects either the segment AB or the segment AD, yielding an intersection point nearer to L than the supposedly nearest intersection point A, thus providing the contradiction.

The difficulties in applying this method are caused in part by the absence of any systematic procedure for devising an extremal problem that leads to the solution of the original question.

Use of figures with special properties. Sometimes a general theorem may be established by the use of appropriate special figures, even if they are not of the kind that the theorem is concerned with. This method is used in considering the question known as Borsuk's problem.

Borsuk's problem on decomposition

The Polish mathematician K. Borsuk proved in 1933 that in any decomposition of the d-dimensional ball B^d into d subsets, at least one of the subsets has a diameter equal to diam B^d; and he asked whether it is possible to decompose every subset A of the d-dimensional space into $d+1$ subsets, each of which has a diameter smaller than diam A. (Such a decomposition is easily found if A is the ball B^d.) In case $d=2$ Borsuk's problem reduces to the question of whether each plane set A may be decomposed into three parts, each of diameter less than diam A. An affirmative answer follows in this case from the fact (which is not hard to prove) that each planar set A with diam $A=1$ may be covered by a regular hexagon H of edge length $1\sqrt{3}=0.577\cdots$ (the diameter of H is diam $H=2\sqrt{3}=1.155\cdots>1$, and the distance between the pairs of parallel sides is 1; see Figure 11). Such a hexagon H may be cut into three pentagons (indicated in Figure 11 by dotted lines), each of which has a diameter of only $\sqrt{3}/2=0.866\cdots<1$. This partition of H may clearly be used to partition each planar set of diameter 1, thus establishing the following stronger variant of Borsuk's problem in the plane: each planar set A may be decomposed into three subsets, each of diameter at most $0.866\cdots\times$(diam A). An affirmative solution of Borsuk's problem in the three-dimensional case may be proved by a similar method, in which the hexagon H is replaced by a polyhedron obtained by appropriate triple truncation of the regular octahedron.

Use of transformations between different spaces and applications of Helly's theorem. Although those two methods do not necessarily go together, both may be illustrated in one example—the proof of theorem D concerning parallel segments. Let the segment I_i have end-points (x_i, y_i) and (x_i, y'_i), where $y_i \leq y'_i$ and $i=1, 2, \cdots, n$. The case that two of the segments are on one line is easily disposed of; so it may be assumed that $x_1, x_2, \cdots, x_n$ are all different. With each straight line $y=ax+b$ in the (x, y)-plane can be associated a point (a, b) in another plane, the (a, b)-plane. Now, for $i=1, 2, \cdots, n$, the set consisting of all those points (a, b) for which the corresponding line $y=ax+b$ in the (x, y) plane meets the

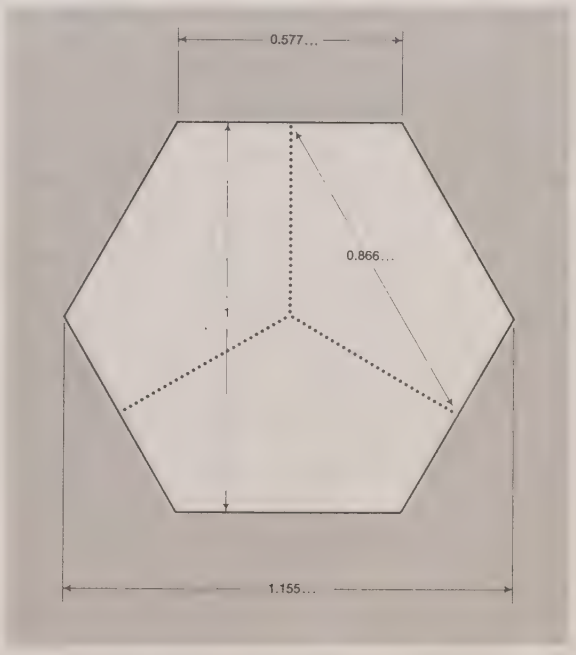

Figure 11: Illustration of Borsuk's problem.

segment I_i can be denoted by K_i. This condition means that $y_i \leq ax_i + b \leq y'_i$, so that each set K_i is convex. The existence of a line intersecting three of the segments I_i means that the corresponding sets K_i have a common point. Then Helly's theorem for the (a, b)-plane implies the existence of a point (a^*, b^*) common to all sets K_i. This in turn means that the line $y = a^*x + b^*$ meets all the segments $I_1, I_2, \cdots, I_n$, and the proof of theorem D is complete.

In addition to the methods illustrated above, many other techniques of proof are used in combinatorial geometry, ranging from simple mathematical induction to sophisticated decidability theorems of formal logic. The variety of methods available and the likelihood that there are many more not yet invented continue to stimulate research in this rapidly developing branch of mathematics. (B.G.)

Issled.,* 15:431–444 (1963), give glimpses of some of the early beginnings of the subject in the Orient. The term combinatorial was first used in GOTTFRIED WILHELM LEIBNIZ, *Dissertatio de arte combinatoria* (1666). W.W. ROUSE BALL, *Mathematical Recreations and Essays,* rev. by H.S. MACDONALD COXETER (1942), contains an account of some of the famous recreational combinatorial problems of the 19th century, such as the problem of eight queens, Hamiltonian circuits, and the Kirkman schoolgirl problem. EUGEN NETTO, *Lehrbuch der Combinatorik,* 2nd ed. (1927, reprinted 1958); and PERCY A. MACMAHON, *Combinatory Analysis,* 2 vol. (1915–16, reprinted 1960), show the state of the subject in the early part of the 20th century. HERBERT J. RYSER, *Combinatorial Mathematics* (1963); MARSHALL HALL, JR., *Combinatorial Theory* (1967); C.L. LIU, *Introduction to Combinatorial Mathematics* (1968), all deal with combinatorics in general. JOHN RIORDAN, *An Introduction to Combinatorial Analysis* (1958); and CLAUDE BERGE, *Principes de combinatoire* (1968; Eng. trans., *Principles of Combinatorics,* 1971), deal with problems of enumeration. CLAUDE BERGE, *Théorie des graphes et ses applications* (1957; Eng. trans., *The Theory of Graphs and Its Applications,* 1962); CLAUDE BERGE and A. GHOUILAHOURI, *Programmes, jeux et réseaux de transport* (1962; Eng. trans., *Programming, Games and Transportation Networks,* 1965); FRANK HARARY, *Graph Theory* (1969), deal with graph theoretic problems. OYSTEIN ORE, *The Four-Color Problem* (1967), gives an introduction to this problem. PETER DEMBOWSKI, *Finite Geometries* (1968), contains most of the important developments on designs, including partially balanced and group divisible designs. ELWYN R. BERLEKAMP, *Algebraic Coding Theory* (1968), may be consulted for combinatorial aspects of coding theory. MARSHALL HALL, JR., "A Survey of Combinatorial Analysis," in *Surveys in Applied Mathematics,* vol. 4 (1958), gives a very good survey of combinatorial developments up to 1958. E.F. BECKENBACH (ed.), *Applied Combinatorial Mathematics* (1964), gives a good idea of the wide range of applications of modern combinatorics. G.C. ROTA, "Combinatorial Analysis," in G.A.W. BOEHM (ed.), *The Mathematical Sciences: A Collection of Essays* (1969), in addition to surveying some of the famous combinatorial problems brings out modern trends and indicates where combinatorics is headed. HUGO HADWIGER and HANS DEBRUNNER, *Combinatorial Geometry in the Plane* (1964); I.M. YAGLOM and V.G. BOLTYANSKY, *Convex Figures* (1961; orig. pub. in Russia, 1951); V.G. BOLTYANSKY, *Equivalent and Equidecomposable Figures* (1963; orig. pub. in Russian, 1956); and L.A. LYUSTERNIK, *Convex Figures and Polyhedra* (1966; orig. pub. in Russian, 1956), deal with aspects of combinatorial geometry on an elementary level. On an advanced level, see H.S. MACDONALD COXETER, *Regular Polytopes,* 2nd ed. (1963); L. FEJES TOTH, *Lagerungen in der Ebene, auf der Kugel und im Raum* (1953) and *Regular Figures* (1964); BRANKO GRUNBAUM, *Convex Polytopes* (1967) and *Arrangements and Spreads* (1972); and C.A. ROGERS, *Packing and Covering* (1964). See also KENNETH P. BOGART, *Introductory Combinatorics* (1983); and R.J. WILSON (ed.), *Applications of Combinatorics* (1982), both accessible to laymen.

Communication

Communication, the exchange of meanings between individuals through a common system of symbols, concerned scholars since the time of ancient Greece. Until modern times, however, the topic was usually subsumed under other disciplines and taken for granted as a natural process inherent to each. In 1928 the English literary critic and author I.A. Richards offered one of the first—and in some ways still the best—definitions of communication as a discrete aspect of human enterprise:

> Communication takes place when one mind so acts upon its environment that another mind is influenced, and in that other mind an experience occurs which is like the experience in the first mind, and is caused in part by that experience.

Richards' definition is both general and rough, but its application to nearly all kinds of communication—including those between humans and animals (but excluding machines)—separated the contents of messages from the processes in human affairs by which these messages are transmitted. More recently, questions have been raised concerning the adequacy of any single definition of the term communication as it is currently employed. The American psychiatrist and scholar Jurgen Ruesch has identified 40 varieties of disciplinary approaches to the subject, including architectural, anthropological, psychological, political, and many other interpretations of the apparently simple interaction described by Richards. In total, if such informal communications as sexual attraction and play behaviour are included, there exist at least 50 modes of interpersonal communication that draw upon dozens of discrete intellectual disciplines and analytic approaches. Communication may therefore be analyzed in at least 50 different ways.

Interest in communication has been stimulated by advances in science and technology, which, by their nature, have called attention to man as a communicating creature. Among the first and most dramatic examples of the inventions resulting from technological ingenuity were the telegraph and telephone, followed by others like wireless radio and telephoto devices. The development of popular newspapers and periodicals, broadcasting, motion pictures, and television led to institutional and cultural innovations that permitted efficient and rapid communication between a few individuals and large populations; these media have been responsible for the rise and social power of the new phenomenon of mass communication. (See also INFORMATION PROCESSING AND INFORMATION SYSTEMS; TELECOMMUNICATIONS SYSTEMS.)

This article is divided into the following sections:

Communication and other disciplines

Since about 1920 the growth and apparent influence of communications technology have attracted the attention of many specialists who have attempted to isolate communication as a specific facet of their particular interest. Psychologists, in their studies of behaviour and mind, have evolved concepts of communication useful to their investigations as well as to certain forms of therapy. Social scientists have identified various forms of communication by which myths, styles of living, mores, and traditions are passed either from generation to generation or from one segment of society to another. Political scientists and economists have recognized that communication of many types lies at the heart of the regularities in the social order. Under the impetus of new technology—particularly high-speed computers—mathematicians and engineers have tried to quantify and measure components of communicated information and to develop methods for translating various types of messages into quantities or amounts amenable to both their procedures and instruments. Numerous and differently phrased questions have been posed by artists, architects, artisans, writers, and others concerning the overall influences of various types of communication. Many researchers, working within the relevant concerns of their disciplines, have also sought possible theories or laws of cause and effect to explain the ways in which human dispositions are affected by certain kinds of communication under certain circumstances, and the reasons for the change.

In the 1960s a Canadian educator, Marshall McLuhan, drew the threads of interest in the field of communication into a view that associated many contemporary psychological and sociological phenomena with the media employed in modern culture. McLuhan's often repeated idea, "the medium is the message," stimulated numerous filmmakers, photographers, artists, and others, who adopted McLuhan's view that contemporary society had moved (or was moving) from a "print" culture to a "visual" one. The particular forms of greatest interest to McLuhan and his followers were those associated with the sophisticated technological instruments for which young people in particular display enthusiasm, namely motion pictures, television, and sound recordings.

Modern interests in communication

By the late 20th century the main focus of interest in communication seemed to be drifting away from McLuhanism and to be centring upon: (1) the mass communication industries, the people who run them, and the effects they have upon their audiences; (2) persuasive communication and the use of technology to influence dispositions; (3) processes of interpersonal communication as mediators of information; (4) dynamics of verbal and nonverbal (and perhaps extrasensory) communication between individuals; (5) perception of different kinds of communications; (6) uses of communication technology for social and artistic purposes, including education in and out of school; and (7) development of relevant criticism for artistic endeavours employing modern communications technology.

In short, a communication expert may be oriented to any of a number of disciplines in a field of inquiry that has, as yet, neither drawn for itself a conclusive roster of subject matter nor agreed upon specific methodologies of analysis.

MODELS OF COMMUNICATION

Fragmentation and problems of interdisciplinary outlook have generated a wide range of discussion concerning the ways in which communication occurs and the processes it entails. Most speculation on these matters admits, in one way or another, that the communication theorist's task is to answer as clearly as possible the question, "*Who* says *what* to *whom* with *what effect?*" (This query was originally posed by the U.S. political scientist Harold D. Lasswell.) Obviously, all of the critical elements in this question may be interpreted differently by scholars and writers in different disciplines.

Linear models. One of the most productive schematic models of a communications system that has been proposed as an answer to Lasswell's question emerged in the late 1940s, largely from the speculations of two U.S. mathematicians, Claude Shannon and Warren Weaver. The simplicity of their model, its clarity, and its surface generality proved attractive to many students of commu-

Shannon's and Weaver's schematic model

nication in a number of disciplines, although it is neither the only model of the communication process extant nor is it universally accepted. As originally conceived, the model contained five elements—an information source, a transmitter, a channel of transmission, a receiver, and a destination—all arranged in linear order. Messages (electronic messages, initially) were supposed to travel along this path, to be changed into electric energy by the transmitter, and to be reconstituted into intelligible language by the receiver. In time, the five elements of the model were renamed so as to specify components for other types of communication transmitted in various manners. The information source was split into its components (both source and message) to provide a wider range of applicability. The six constituents of the revised model are: (1) a source, (2) an encoder, (3) a message, (4) a channel, (5) a decoder, and (6) a receiver. For some communication systems, the components are as simple to specify as, for instance, (1) a man on the telephone, (2) the mouthpiece of the telephone, (3) the words the man speaks, (4) the electrical wires along which the words (now electrical impulses) travel, (5) the earpiece of another telephone, and (6) the mind of the listener. In other communication systems, the components are more difficult to isolate; *e.g.,* the communication of the emotions of a fine artist by means of a painting to people who may respond to the message long after the artist's death.

Begging a multitude of psychological, aesthetic, and sociological questions concerning the exact nature of each component, the linear model appeared, from the commonsense perspective, at least, to explain in general terms the ways in which certain classes of communication occurred. It did not indicate the reason for the inability of certain communications—obvious in daily life—to fit its neat paradigm.

Entropy, negative entropy, and redundancy. Another concept, first called by Shannon a "noise source" but later associated with the notion of entropy (a principle derived from physics), was imposed upon the communication model. Entropy is analogous in most communication to audio or visual static—that is, to outside influences that diminish the integrity of the communication and, possibly, distort the message for the receiver. Negative entropy may also occur in instances in which incomplete or blurred messages are nevertheless received intact, either because of the ability of the receiver to fill in missing details or to recognize, despite distortion or a paucity of information, both the intent and content of the communication.

Although rarely shown on diagrammatic models of this version of the communication process, redundancy—the repetition of elements within a message that prevents the failure of communication of information—is the greatest antidote to entropy. Most written and spoken languages, for example, are roughly half-redundant. If 50 percent of the words of this article were taken away at random, there would still remain an intelligible—although somewhat peculiar—essay. Similarly, if one-half of the words of a radio news commentator are heard, the broadcast can usually be understood. Redundancy is apparently involved in most human activities, and, because it helps to overcome the various forms of entropy that tend to turn intelligible messages into unintelligible ones (including psychological entropy on the part of the receiver), it is an indispensable element for effective communication.

Messages are therefore susceptible to considerable modification and mediation. Entropy distorts, while negative entropy and redundancy clarify; as each occurs differentially in the communication process, the chances of the message being received and correctly understood vary. Still, the process (and the model of it) remains conceptually static, because it is fundamentally concerned with messages sent from point to point, and not with their results or possible influences upon sender and receiver.

Feedback. To correct this flaw, the principle of feedback was added to the model and provided a closer approximation of interpersonal human interaction than was known theretofore. This construct was derived from the studies of Norbert Wiener, the so-called father of the science of cybernetics. Wiener's cybernetic models, some of which provide the basis for current computer technology, were designed to be responsive to their own behaviour; that is, they audited their own performances mathematically or electronically in order to avoid errors of entropy, unnecessary redundancy, or other simple hazards.

Aspects of feedback

Certain types of common communications—Christmas cards, for instance—usually require little feedback. Others, particularly interactions between human beings in conversation, cannot function without the ability of the message sender to weigh and calculate the apparent effect of his words on his listener. It is largely the aspect of feedback that provides for this model the qualities of a process, because each instance of feedback conditions or alters the subsequent messages.

Dynamic models. Other models of communication processes have been constructed to meet the needs of students of communication whose interests differ from those of quantitatively oriented theorists like Shannon, Weaver, and Wiener. While the model described above displays some generality and shows simplicity, it lacks some of the predictive, descriptive, and analytic powers found in other approaches. A psychologist, Theodore M. Newcomb, for example, has articulated a more fluid system of dimensions to represent the individual interacting in his environment. Newcomb's model and others similar to it are not as precisely mathematical (quantitative) as Shannon's and thus permit more flexible accounts of human behaviour and its variable relationships. They do not deny the relevance of linear models to Shannon and Weaver's main concerns—quanta of information and the delivery of messages under controlled conditions—but they question their completeness and utility in describing cognitive, emotional, and artistic aspects of communication as they occur in sociocultural matrices.

Students concerned mainly with persuasive and artistic communication often centre attention upon different kinds, or modes, of communication (*i.e.,* narrative, pictorial, and dramatic) and theorize that the messages they contain, including messages of emotional quality and artistic content, are communicated in various manners to and from different sorts of people. For them, the stability and function of channel or medium are more variable and less mechanistically related to the process than they are for followers of Shannon and Weaver and psychologists like Newcomb. (McLuhan, indeed, asserts that the channel actually dictates, or severely influences, the message—both as sent and received.) Many analysts of communication, linguistic philosophers, and others are concerned with the nature of messages, particularly their compatibility with sense and emotion, their style, and the intentions behind them. They find both linear and geometric models of process of little interest to their concerns, although considerations related to these models, particularly those of entropy, redundancy, and feedback, have provided significant and productive concepts for most students of communication.

Applications of formal logic and mathematics. Despite the numerous types of communication or information theory extant today—and those likely to be formulated tomorrow—the most rationally and experimentally consistent approaches to communication theory so far developed follow the constructions of Shannon and others described above. Such approaches tend to employ the structural rigours of logic rather than the looser syntaxes, grammars, and vocabularies of common languages, with their symbolic, poetic, and inferential aspects of meaning.

Cybernetic theory and computer technology require rigorous but straightforward languages to permit translation into nonambiguous, special symbols that can be stored and utilized for statistical manipulations. The closed system of formal logic proved ideal for this need. Premises and conclusions drawn from syllogisms according to logical rules may be easily tested in a consistent, scientific manner, as long as all parties communicating share the rational premises employed by the particular system.

Formal logic, syllogisms, and communication

That this logical mode of communication drew its frame of discourse from the logic of the ancient Greeks was inevitable. Translated into an Aristotelian manner of discourse, meaningful interactions between individuals could be transferred to an equally rational closed system of

mathematics: an arithmetic for simple transactions, an algebra for solving certain well-delimited puzzles, a calculus to simulate changes, rates and flows, and a geometry for purposes of illustration and model construction. This progression has proved quite useful for handling those limited classes of communications that arise out of certain structured, rational operations, like those in economics, inductively oriented sociology, experimental psychology, and other behavioral and social sciences, as well as in most of the natural sciences.

The basic theorem of information theory rests, first, upon the assumption that the message transmitted is well organized, consistent, and characterized by relatively low and determinable degrees of entropy and redundancy. (Otherwise, the mathematical structure might yield only probability statements approaching random scatters, of little use to anyone.) Under these circumstances, by devising proper coding procedures for the transmitter, it becomes possible to transmit symbols over a channel at an average rate that is nearly the capacity of units per second of the channel (symbolized by C) as a function of the units per second from an information source (H)—but never at rates in excess of capacity divided by units per second (C/H), no matter how expertly the symbols are coded. As simple as this notion seems, upon determining the capacity of the channel and by cleverly coding the information involved, precise mathematical models of information transactions (similar to electronic frequencies of energy transmissions) may be evolved and employed for complex analyses within the strictures of formal logic. They must, of course, take into account as precisely as possible levels of entropy and redundancy as well as other known variables.

The internal capacities of the channel studied and the sophistication of the coding procedures that handle the information limit the usefulness of the theorem presented above. At present such procedures, while they may theoretically offer broad prospects, are restricted by formal encoding procedures that depend upon the capacities of the instruments in which they are stored (nowadays, mostly on magnetic tape and disk-packs in computers). Although such devices can handle quickly the logic of vast amounts of relatively simple information, they cannot match the flexibility and complexity of the human brain, still man's prime instrument for managing the subtleties of most communication.

TYPES OF COMMUNICATION

Signals, signs, and symbols

Nonvocal communication. Signals, signs, and symbols, three related components of communication processes found in all known cultures, have attracted considerable scholarly attention because they do not relate primarily to the usual conception of words or language. Each is apparently an increasingly more complex modification of the former, and each was probably developed in the depths of prehistory before, or at the start of, man's early experiments with vocal language.

Signals. A signal may be considered as an interruption in a field of constant energy transfer. An example is the dots and dashes that open and close the electromagnetic field of a telegraph circuit. Such interruptions do not require the construction of a man-made field; interruptions in nature (*e.g.*, the tapping of a pencil in a silent room, or puffs of smoke rising from a mountain top) may produce the same result. The basic function of such signals is to provide the change of a single environmental factor in order to attract attention and to transfer meaning. A code system that refers interruptions to some form of meaningful language may easily be developed with a crude vocabulary of dots, dashes, or other elemental audio and visual articulations. Taken by themselves, the interruptions have a potential breadth of meaning that seems extremely small; they may indicate the presence of an individual in a room, his impatience, agreement, or disagreement with some aspect of his environment or, in the case of a scream for help, a critical situation demanding attention. Coded to refer to spoken or written language, their potential to communicate language is extremely great.

Signs. While signs are usually less germane to the development of words than signals, most of them contain greater amounts of meaning of and by themselves. Ashley Montagu, an anthropologist, has defined a sign as a "concrete denoter" possessing an inherent specific meaning, roughly analogous to the sentence "This is it; do something about it!" The most common signs encountered in daily life are pictures or drawings, although a human posture like a clenched fist, an outstretched arm, or a hand posed in a "Stop" gesture may also serve as signs. The main difference between a sign and a signal is that a sign (like a policeman's badge) contains meanings of an intrinsic nature; a signal (like a scream for help) is merely a device by which one is able to formulate extrinsic meanings. Their difference is illustrated by the observation that many types of animals respond to signals, while only a few intelligent and trained animals (usually dogs and apes) are competent to respond even to simple signs.

All known cultures utilize signs to convey relatively simple messages swiftly and conveniently. Signs may depend for their meaning upon their form, setting, colour, or location. In the United States, traffic signs, uniforms, badges, and barber poles are frequently encountered signs. Taken en masse, any society's lexicon of signs makes up a rich vocabulary of colourful communications.

Symbols. Symbols are more difficult than signs to understand and to define because, unlike signs and signals, they are intricately woven into an individual's ongoing perceptions of the world. They appear to contain a dimly understood capacity that (as one of their functions), in fact, defines the very reality of that world. The symbol has been defined as any device with which an abstraction can be made. Although far from being a precise construction, it leads in a profitable direction. The abstractions of the values that people imbue in other people and in things they own and use lie at the heart of symbolism. Here is a process, according to the British philosopher Alfred North Whitehead, whereby

> some components of [the mind's] experience elicit consciousness, beliefs, emotions, and usages respecting other components of experience.

In Whitehead's opinion, symbols are analogues or metaphors (that may include written and spoken language as well as visual objects) standing for some quality of reality that is enhanced in importance or value by the process of symbolization itself.

Symbol systems in all societies

Almost every society has evolved a symbol system whereby, at first glance, strange objects and odd types of behaviour appear to the outside observer to have irrational meanings and seem to evoke odd, unwarranted cognitions and emotions. Upon examination each symbol system reflects a specific cultural logic, and every symbol functions to communicate information between members of the culture in much the same way as, but in a more subtle manner than, conventional language. Although a symbol may take the form of as discrete an object as a wedding ring or a totem pole, symbols tend to appear in clusters and depend upon one another for their accretion of meaning and value. They are not a language of and by themselves; rather they are devices by which ideas too difficult, dangerous, or inconvenient to articulate in common language are transmitted between people who have acculturated in common ways. It does not appear possible to compile discrete vocabularies of symbols, because they lack the precision and regularities present in natural language that are necessary for explicit definitions.

Icons. Rich clusters of related and unrelated symbols are usually regarded as icons. They are actually groups of interactive symbols, like the White House in Washington, D.C., a funeral ceremony, or an Impressionist painting. Although in examples such as these, there is a tendency to isolate icons and individual symbols for examination, symbolic communication is so closely allied to all forms of human activity that it is generally and nonconsciously used and treated by most people as the most important aspect of communication in society. With the recognition that spoken and written words and numbers themselves constitute symbolic metaphors, their critical roles in the worlds of science, mathematics, literature, and art can be understood. In addition, with these symbols, an individual is able to define his own identity.

Gestures. Professional actors and dancers have known since antiquity that body gestures may also generate a vocabulary of communication more or less unique to each culture. Some U.S. scholars have tried to develop a vocabulary of body language, called kinesics. The results of their investigations, both amusing and potentially practical, may eventually produce a genuine lexicon of American gestures similar to one prepared in detail by François Delsarte, a 19th-century French teacher of pantomime and gymnastics who described the ingenious and complex language of contemporary face and body positions for theatrical purposes.

Proxemics. Of more general, cross-cultural significance are the theories involved in the study of "proxemics" developed by a U.S. anthropologist, Edward Hall. Proxemics involves the ways in which people in various cultures utilize both time and space as well as body positions and other factors for purposes of communication. Hall's "silent language" of nonverbal communications consists of such culturally determined interactions as the physical distance or closeness maintained between individuals, the body heat they give off, odours they perceive in social situations, angles of vision they maintain while talking, the pace of their behaviour, and the sense of time appropriate for communicating under differing conditions. By comparing matters like these in the behaviour of different social classes (and in varying relationships), Hall elaborated and codified a number of sophisticated general principles that demonstrate how certain kinds of nonverbal communication occur. Although Hall's most impressive arguments are almost entirely empirical, and many of them are open to question, the study of proxemics does succeed in calling attention to major features of communication dynamics rarely considered by linguists and symbologists. Students of words have been more interested in objective formal vocabularies than in the more subtle means of discourse unknowingly acquired by the members of a culture.

Vocal communication. Significant differences between nonvocal and vocal communication are matters more of degree than of kind. Signs, signals, symbols, and possibly icons may, at times, be easily verbalized, although most people tend to think of them as visual means of expression. Kinesics and proxemics may also, in certain instances, involve vocalizations as accompaniments to nonverbal phenomena or as somehow integral to them. Be they grunts, words, or sentences, their function is to help in forwarding a communication that is fundamentally nonverbal.

Origins of speech

Although there is no shortage of speculation on the issue, the origins of human speech remain obscure at present. It is plausible that man is born with an instinct for speech. A phenomenon supporting this belief is the presence of unlearned cries and gurgles of infants operating as crude, vocal signs directed to others the baby cannot possibly be aware of. Some anthropologists claim that within the vocabularies of kinesics and proxemics are the virtual building blocks of spoken language; they postulate that primitive men made various and ingenious inventions (including speech) as a result of their need to communicate with others in order to pool their intellectual and physical resources. Other observers suggest similar origins of speech, including the vocalization of physical activity, imitation of the sounds of nature, and sheer serendipity. Scientific proof of any of these speculations is at present impossible.

Not only is the origin of speech disputed among experts but the precise reasons for the existence of the numerous languages of the world are also far from clear. In the 1920s, an American linguistic anthropologist, Edward Sapir, and, later Benjamin Lee Whorf, centred attention upon the various methods of expression found in different cultures. Drawing their evidence primarily from the languages of primitive societies, they made some very significant observations concerning spoken (and probably written) language. First, man's language reflects in subtle ways those matters of greatest relevance and importance to the value system of each particular culture. Thus, language may be said to reflect culture, or, in other words, people seem to find ways of saying what they need to say. A familiar illustration is the many words (or variations of words) that Eskimos use to describe whale blubber in its various states; *e.g.*, on the whale, ready to eat, raw, cooked, rancid. Another example is the observation that "drunk" possesses more synonyms than any other term in the English language. Apparently, this is the result of a psychological necessity to euphemize a somewhat nasty, uncomfortable, or taboo matter, a device also employed for other words that describe seemingly important, but improper, behaviour or facets of culture.

Need for euphemisms

Adaptability of language. Other observations involve the discovery that any known language may be employed, without major modification, to say almost anything that may be said in any other language. A high degree of circumlocution and some nonverbal vocalization may be required to accomplish this end, but, no matter how alien the concept to the original language, it may be expressed clearly in the language of another culture. Students of linguistic anthropology have been able to describe adequately in English esoteric linguistic propositions of primitive societies, just as it has been possible for anthropologists to describe details of Western technology to natives in remote cultures. Understood as an artifact of culture, spoken language may therefore be considered as a universal channel of communication into which various societies dip differentially in order to expedite and specify the numerous points of contact between individuals.

Language remains, however, a still partially understood phenomenon used to transact several types of discourse. Language has been classified on the basis of several criteria. One scheme established four categories on the basis of informative, dynamic, emotive, and aesthetic functions. Informative communication deals largely with narrative aspects of meaning; dynamic discourse concerns the transaction of dispositions such as opinions and attitudes; the emotive employment of language involves the evocation of feeling states in others in order to impel them to action; and aesthetic discourse, usually regarded as a poetic quality in speech, conveys stylistic aspects of expression.

Laughter. Although most vocal sounds other than words are usually considered prelinguistic language, the phenomenon of laughter as a form of communication is in a category by itself, with its closest relative being its apparent opposite, crying. Contemporary ethologists, like Konrad Lorenz, have attempted to associate laughter with group behaviour among animals in instances in which aggression is thwarted and laughlike phenomena seem to result among herds. Lorenz's metaphors, while apparently reasonable, cannot be verified inductively. They seem less reasonable to many than the more common notions of Freud and others that laughter either results from, or is related to, the nonconscious reduction of tensions or inhibitions. Developed as a form of self-generated pleasure in the infant and rewarded both physically and psychologically by feelings of gratification, laughter provides a highly effective, useful, and contagious means of vocal communication. It deals with a wide range of cultural problems, often more effectively than speech, in much the same manner that crying, an infantile, probably instinctive reaction to discomfort, communicates an unmistakable emotional state to others.

The reasons for laughter in complex social situations is another question and is answered differently by philosophers and psychologists. The English novelist George Meredith proposed a theory, resulting from his analysis of 18th-century French court comedies, that laughter serves as an enjoyable social corrective. The two best known modern theories of the social wellsprings of laughter are the philosopher Henri Bergson's hypothesis that laughter is a form of rebellion against the mechanization of human behaviour and nature, and Freud's concept of laughter as repressed sexual feeling. The writer Arthur Koestler regarded laughter as a means of individual enlightenment, revelation, and subsequent freedom from confusion or misunderstanding concerning some part of the environment.

Man's vocal instrument as a device of communication represents an apex of physical and intellectual evolution. It can express the most basic instinctual demands as well as a range of highly intellectual processes, including the possible mastery of numerous complex languages, each

Capacities of the vocal organs

with an enormous vocabulary. Because of the imitative capacity of the vocal mechanism (including its cortical directors), suitably talented individuals can simulate the sounds of nature in song, can communicate in simple ways with animals, and can indulge in such tricks as ventriloquism and the mimicry of other voices. Recent tape recording techniques have even extended this flexibility into new domains, allowing singers to accompany their own voices in different keys to produce effects of duets or choruses composed electronically from one person's voice.

Mass and public communication. *Prerequisites for mass communication.* The technology of modern mass communication results from the confluence of many types of inventions and discoveries, some of which (the printing press, for instance) actually preceded the Industrial Revolution. Technological ingenuity of the 19th and 20th centuries has developed the newer means of mass communication, particularly broadcasting, without which the present near-global diffusion of printed words, pictures, and sounds would have been impossible. The steam printing press, radio, motion pictures, television, and sound recording—as well as systems of mass production and distribution—were necessary before public communication in its present form might occur.

Technology was not, however, the only prerequisite for the development of mass communication in the West. A large public of literate citizens was necessary before giant publishing and newspaper empires might employ extant communications technology to satisfy widespread desires or needs for popular reading materials. Affluence and interest were (and are) prerequisites for the maintenance of the radio, television, cinema, and recording industries, institutions that are presently most highly developed in wealthy, industrial nations. Even in countries in which public communication is employed largely for government propaganda, certain minimal economic and educational standards must be achieved before this persuasion is accepted by the general public.

Control of mass communication. Over the years, control of the instruments of mass communication has fallen into the hands of relatively small (some claim diminishing) numbers of professional communicators who seem, as populations expand and interest widens, to reach ever increasing numbers of people. In the United States, for example, far fewer newspapers currently serve more readers than ever before, three television networks are predominant, and a handful of book publishers produce the majority of the best-sellers.

Public communicators are not entirely free to follow their own whims in serving the masses, however. As is the case of any market, consumer satisfaction (or the lack of it) limits the nature and quantity of the material produced and circulated. Mass communicators are also restricted in some measure by laws governing libel, slander, and invasion of privacy and, in most countries, by traditions of professionalism that entail obligations of those who maintain access to the public's eyes and ears. In almost every modern nation, privileges to use broadcasting frequencies are circumscribed either loosely or rigidly by government regulations. In some countries, national agencies exercise absolute control of all broadcasting, and in certain areas print and film media operate under strict government control. Written and film communications may be subject to local legal restraints in regard to censorship and have restrictions similar to those of other private businesses. Traditions of decorum and self-censorship, however, apply variably to publishers and filmmakers, depending usually upon the particular markets to which their fare is directed.

Opinions on the effect of public communication

Effects of mass communication. Lively controversy centres on the effect of public communication upon audiences, not only in matters concerning public opinion on political issues but in matters of personal life-styles and tastes, consumer behaviour, the sensibilities and dispositions of children, and possible inducements to violence. Feelings regarding these matters vary greatly. Some people construe the overall effects of mass communication as generally harmless to both young and old. Many sociologists follow the theory that mass communication seems to influence attitudes and behaviour only insofar as it confirms the status quo—*i.e.*, it influences values already accepted and operating in the culture. Numerous other analysts, usually oriented to psychological or psychiatric disciplines, believe that mass communications provide potent sources of informal education and persuasion. Their conclusions are drawn largely from observations that many, or most, people in technological societies form their personal views of the social realities beyond their immediate experience from messages presented to them through public communication.

To assume that public communication is predominantly reflective of current values, morals, and attitudes denies much common experience. Fashions, fads, and small talk are too obviously and directly influenced by material in the press, in films, and in television to support this view. The success of public communication as an instrument of commercial advertising has also been constant and noticeable. Present evidence indicates that various instruments of mass communication produce varying effects upon different segments of the audience. These effects seem too numerous and short-lived to be measured effectively with currently available instruments. Much of the enormous output on television and radio and in print is probably simply regarded as "play" and of little consequence in affecting adult dispositions, although many psychologists believe that the nature of children's play experiences is critical to their maturation.

The role of newspapers, periodicals, and television in influencing political opinion is fairly well established in the voting behaviour of the so-called undecided voters. Numerous studies have shown that while the majority of citizens in the United States cast their votes along party lines and according to social, educational, and economic determinants, middle-of-the-road voters often hold the balance of power that determines the outcomes of elections. Politicians have become sensitive to their television images and have devised much of their campaign strategy with the television audience in mind. Advertising agencies familiar with television techniques have been brought into the political arena to plan campaigns and develop their clients' images. The effectiveness of television campaigning cannot yet be determined reliably.

Public communication is a near-ubiquitous condition of modernity. Most reliable surveys show that the majority of the people of the world (including those of totalitarian countries) are usually satisfied with the kind of mass communication available to them. Lacking alternatives to the communication that they easily and conveniently receive, most people seem to accept what they are given without complaint. Mass communication is but one facet of life for most individuals, whose main preoccupations centre on the home and on daily employment. Public communication is an inexpensive addendum to living, usually directed to low common denominators of taste, interest, and refinement of perception. Although mass communication places enormous potential power in the hands of relatively few people, traditional requirements for popular approval and assent have prevented its use for overt subversion of culturally sanctioned institutions. Fear of such subversion is sometimes expressed by critics.

Role of popular approval

THE PSYCHOLOGY OF COMMUNICATION

Contemporary psychologists have, since World War II, shown considerable interest in the ways in which communications occur. Behaviourists have been prone to view communication in terms of stimulus–response relationships between sources of communications and individuals or groups that receive them. Those who subscribe to Freud's analysis of group psychology and ego theory tend to regard interactions in communication as reverberations of family group dynamics experienced early in life.

By the middle 1950s, psychological interest settled largely on the persuasive aspects of various types of messages. Psychologists have attempted to discover whether a general factor of personality called "persuasibility" might be identified in people at large. It would appear, though with qualifications, that individuals are indeed variably persuasible and that, at times, factors of personality are related to this quality.

Gestures. Professional actors and dancers have known since antiquity that body gestures may also generate a vocabulary of communication more or less unique to each culture. Some U.S. scholars have tried to develop a vocabulary of body language, called kinesics. The results of their investigations, both amusing and potentially practical, may eventually produce a genuine lexicon of American gestures similar to one prepared in detail by François Delsarte, a 19th-century French teacher of pantomime and gymnastics who described the ingenious and complex language of contemporary face and body positions for theatrical purposes.

Proxemics. Of more general, cross-cultural significance are the theories involved in the study of "proxemics" developed by a U.S. anthropologist, Edward Hall. Proxemics involves the ways in which people in various cultures utilize both time and space as well as body positions and other factors for purposes of communication. Hall's "silent language" of nonverbal communications consists of such culturally determined interactions as the physical distance or closeness maintained between individuals, the body heat they give off, odours they perceive in social situations, angles of vision they maintain while talking, the pace of their behaviour, and the sense of time appropriate for communicating under differing conditions. By comparing matters like these in the behaviour of different social classes (and in varying relationships), Hall elaborated and codified a number of sophisticated general principles that demonstrate how certain kinds of nonverbal communication occur. Although Hall's most impressive arguments are almost entirely empirical, and many of them are open to question, the study of proxemics does succeed in calling attention to major features of communication dynamics rarely considered by linguists and symbologists. Students of words have been more interested in objective formal vocabularies than in the more subtle means of discourse unknowingly acquired by the members of a culture.

Vocal communication. Significant differences between nonvocal and vocal communication are matters more of degree than of kind. Signs, signals, symbols, and possibly icons may, at times, be easily verbalized, although most people tend to think of them as visual means of expression. Kinesics and proxemics may also, in certain instances, involve vocalizations as accompaniments to nonverbal phenomena or as somehow integral to them. Be they grunts, words, or sentences, their function is to help in forwarding a communication that is fundamentally nonverbal.

Origins of speech

Although there is no shortage of speculation on the issue, the origins of human speech remain obscure at present. It is plausible that man is born with an instinct for speech. A phenomenon supporting this belief is the presence of unlearned cries and gurgles of infants operating as crude, vocal signs directed to others the baby cannot possibly be aware of. Some anthropologists claim that within the vocabularies of kinesics and proxemics are the virtual building blocks of spoken language; they postulate that primitive men made various and ingenious inventions (including speech) as a result of their need to communicate with others in order to pool their intellectual and physical resources. Other observers suggest similar origins of speech, including the vocalization of physical activity, imitation of the sounds of nature, and sheer serendipity. Scientific proof of any of these speculations is at present impossible.

Not only is the origin of speech disputed among experts but the precise reasons for the existence of the numerous languages of the world are also far from clear. In the 1920s, an American linguistic anthropologist, Edward Sapir, and, later Benjamin Lee Whorf, centred attention upon the various methods of expression found in different cultures. Drawing their evidence primarily from the languages of primitive societies, they made some very significant observations concerning spoken (and probably written) language. First, man's language reflects in subtle ways those matters of greatest relevance and importance to the value system of each particular culture. Thus, language may be said to reflect culture, or, in other words, people seem to find ways of saying what they need to say. A familiar illustration is the many words (or variations of words) that Eskimos use to describe whale blubber in its various states; *e.g.,* on the whale, ready to eat, raw, cooked, rancid. Another example is the observation that "drunk" possesses more synonyms than any other term in the English language. Apparently, this is the result of a psychological necessity to euphemize a somewhat nasty, uncomfortable, or taboo matter, a device also employed for other words that describe seemingly important, but improper, behaviour or facets of culture.

Need for euphemisms

Adaptability of language. Other observations involve the discovery that any known language may be employed, without major modification, to say almost anything that may be said in any other language. A high degree of circumlocution and some nonverbal vocalization may be required to accomplish this end, but, no matter how alien the concept to the original language, it may be expressed clearly in the language of another culture. Students of linguistic anthropology have been able to describe adequately in English esoteric linguistic propositions of primitive societies, just as it has been possible for anthropologists to describe details of Western technology to natives in remote cultures. Understood as an artifact of culture, spoken language may therefore be considered as a universal channel of communication into which various societies dip differentially in order to expedite and specify the numerous points of contact between individuals.

Language remains, however, a still partially understood phenomenon used to transact several types of discourse. Language has been classified on the basis of several criteria. One scheme established four categories on the basis of informative, dynamic, emotive, and aesthetic functions. Informative communication deals largely with narrative aspects of meaning; dynamic discourse concerns the transaction of dispositions such as opinions and attitudes; the emotive employment of language involves the evocation of feeling states in others in order to impel them to action; and aesthetic discourse, usually regarded as a poetic quality in speech, conveys stylistic aspects of expression.

Laughter. Although most vocal sounds other than words are usually considered prelinguistic language, the phenomenon of laughter as a form of communication is in a category by itself, with its closest relative being its apparent opposite, crying. Contemporary ethologists, like Konrad Lorenz, have attempted to associate laughter with group behaviour among animals in instances in which aggression is thwarted and laughlike phenomena seem to result among herds. Lorenz's metaphors, while apparently reasonable, cannot be verified inductively. They seem less reasonable to many than the more common notions of Freud and others that laughter either results from, or is related to, the nonconscious reduction of tensions or inhibitions. Developed as a form of self-generated pleasure in the infant and rewarded both physically and psychologically by feelings of gratification, laughter provides a highly effective, useful, and contagious means of vocal communication. It deals with a wide range of cultural problems, often more effectively than speech, in much the same manner that crying, an infantile, probably instinctive reaction to discomfort, communicates an unmistakable emotional state to others.

The reasons for laughter in complex social situations is another question and is answered differently by philosophers and psychologists. The English novelist George Meredith proposed a theory, resulting from his analysis of 18th-century French court comedies, that laughter serves as an enjoyable social corrective. The two best known modern theories of the social wellsprings of laughter are the philosopher Henri Bergson's hypothesis that laughter is a form of rebellion against the mechanization of human behaviour and nature, and Freud's concept of laughter as repressed sexual feeling. The writer Arthur Koestler regarded laughter as a means of individual enlightenment, revelation, and subsequent freedom from confusion or misunderstanding concerning some part of the environment.

Man's vocal instrument as a device of communication represents an apex of physical and intellectual evolution. It can express the most basic instinctual demands as well as a range of highly intellectual processes, including the possible mastery of numerous complex languages, each

Capacities of the vocal organs

with an enormous vocabulary. Because of the imitative capacity of the vocal mechanism (including its cortical directors), suitably talented individuals can simulate the sounds of nature in song, can communicate in simple ways with animals, and can indulge in such tricks as ventriloquism and the mimicry of other voices. Recent tape recording techniques have even extended this flexibility into new domains, allowing singers to accompany their own voices in different keys to produce effects of duets or choruses composed electronically from one person's voice.

Mass and public communication. *Prerequisites for mass communication.* The technology of modern mass communication results from the confluence of many types of inventions and discoveries, some of which (the printing press, for instance) actually preceded the Industrial Revolution. Technological ingenuity of the 19th and 20th centuries has developed the newer means of mass communication, particularly broadcasting, without which the present near-global diffusion of printed words, pictures, and sounds would have been impossible. The steam printing press, radio, motion pictures, television, and sound recording—as well as systems of mass production and distribution—were necessary before public communication in its present form might occur.

Technology was not, however, the only prerequisite for the development of mass communication in the West. A large public of literate citizens was necessary before giant publishing and newspaper empires might employ extant communications technology to satisfy widespread desires or needs for popular reading materials. Affluence and interest were (and are) prerequisites for the maintenance of the radio, television, cinema, and recording industries, institutions that are presently most highly developed in wealthy, industrial nations. Even in countries in which public communication is employed largely for government propaganda, certain minimal economic and educational standards must be achieved before this persuasion is accepted by the general public.

Control of mass communication. Over the years, control of the instruments of mass communication has fallen into the hands of relatively small (some claim diminishing) numbers of professional communicators who seem, as populations expand and interest widens, to reach ever increasing numbers of people. In the United States, for example, far fewer newspapers currently serve more readers than ever before, three television networks are predominant, and a handful of book publishers produce the majority of the best-sellers.

Public communicators are not entirely free to follow their own whims in serving the masses, however. As is the case of any market, consumer satisfaction (or the lack of it) limits the nature and quantity of the material produced and circulated. Mass communicators are also restricted in some measure by laws governing libel, slander, and invasion of privacy and, in most countries, by traditions of professionalism that entail obligations of those who maintain access to the public's eyes and ears. In almost every modern nation, privileges to use broadcasting frequencies are circumscribed either loosely or rigidly by government regulations. In some countries, national agencies exercise absolute control of all broadcasting, and in certain areas print and film media operate under strict government control. Written and film communications may be subject to local legal restraints in regard to censorship and have restrictions similar to those of other private businesses. Traditions of decorum and self-censorship, however, apply variably to publishers and filmmakers, depending usually upon the particular markets to which their fare is directed.

Opinions on the effect of public communication

Effects of mass communication. Lively controversy centres on the effect of public communication upon audiences, not only in matters concerning public opinion on political issues but in matters of personal life-styles and tastes, consumer behaviour, the sensibilities and dispositions of children, and possible inducements to violence. Feelings regarding these matters vary greatly. Some people construe the overall effects of mass communication as generally harmless to both young and old. Many sociologists follow the theory that mass communication seems to influence attitudes and behaviour only insofar as it confirms the status quo—*i.e.*, it influences values already accepted and operating in the culture. Their conclusions are drawn largely from observations that many, or most, people in technological societies form their personal views of the social realities beyond their immediate experience from messages presented to them through public communication.

To assume that public communication is predominantly reflective of current values, morals, and attitudes denies much common experience. Fashions, fads, and small talk are too obviously and directly influenced by material in the press, in films, and in television to support this view. The success of public communication as an instrument of commercial advertising has also been constant and noticeable. Present evidence indicates that various instruments of mass communication produce varying effects upon different segments of the audience. These effects seem too numerous and short-lived to be measured effectively with currently available instruments. Much of the enormous output on television and radio and in print is probably simply regarded as "play" and of little consequence in affecting adult dispositions, although many psychologists believe that the nature of children's play experiences is critical to their maturation.

The role of newspapers, periodicals, and television in influencing political opinion is fairly well established in the voting behaviour of the so-called undecided voters. Numerous studies have shown that while the majority of citizens in the United States cast their votes along party lines and according to social, educational, and economic determinants, middle-of-the-road voters often hold the balance of power that determines the outcomes of elections. Politicians have become sensitive to their television images and have devised much of their campaign strategy with the television audience in mind. Advertising agencies familiar with television techniques have been brought into the political arena to plan campaigns and develop their clients' images. The effectiveness of television campaigning cannot yet be determined reliably.

Public communication is a near-ubiquitous condition of modernity. Most reliable surveys show that the majority of the people of the world (including those of totalitarian countries) are usually satisfied with the kind of mass communication available to them. Lacking alternatives to the communication that they easily and conveniently receive, most people seem to accept what they are given without complaint. Mass communication is but one facet of life for most individuals, whose main preoccupations centre on the home and on daily employment. Public communication is an inexpensive addendum to living, usually directed to low common denominators of taste, interest, and refinement of perception. Although mass communication places enormous potential power in the hands of relatively few people, traditional requirements for popular approval and assent have prevented its use for overt subversion of culturally sanctioned institutions. Fear of such subversion is sometimes expressed by critics.

Role of popular approval

THE PSYCHOLOGY OF COMMUNICATION

Contemporary psychologists have, since World War II, shown considerable interest in the ways in which communications occur. Behaviourists have been prone to view communication in terms of stimulus–response relationships between sources of communications and individuals or groups that receive them. Those who subscribe to Freud's analysis of group psychology and ego theory tend to regard interactions in communication as reverberations of family group dynamics experienced early in life.

By the middle 1950s, psychological interest settled largely on the persuasive aspects of various types of messages. Psychologists have attempted to discover whether a general factor of personality called "persuasibility" might be identified in people at large. It would appear, though with qualifications, that individuals are indeed variably persuasible and that, at times, factors of personality are related to this quality.

were invented in the 1950s for easier, faster programming; along with them came the need for compilers, programs that translate high-level language programs into machine code. As programming languages became more powerful and abstract, building efficient compilers that create high-quality code in terms of execution speed and storage consumption became an interesting computer science problem in itself.

Increasing use of computers in the early 1960s provided the impetus for the development of operating systems, which consist of system-resident software that automatically handles input and output and the execution of jobs. The historical development of operating systems is summarized below under that topic. Throughout the history of computers, the machines have been utilized in two major applications: (1) computational support of scientific and engineering disciplines and (2) data processing for business needs. The demand for better computational techniques led to a resurgence of interest in numerical methods and their analysis, an area of mathematics that can be traced to the methods devised several centuries ago by physicists for the hand computations they made to validate their theories. Improved methods of computation had the obvious potential to revolutionize how business is conducted, and in pursuit of these business applications new information systems were developed in the 1950s that consisted of files of records stored on magnetic tape. The invention of magnetic-disk storage, which allows rapid access to an arbitrary record on the disk, led not only to more cleverly designed file systems but also, in the 1960s and '70s, to the concept of the database and the development of the sophisticated database management systems now commonly in use. Data structures, and the development of optimal algorithms for inserting, deleting, and locating data, have constituted major areas of theoretical computer science since its beginnings because of the heavy use of such structures by virtually all computer software—notably compilers, operating systems, and file systems. Another goal of computer science is the creation of machines capable of carrying out tasks that are typically thought of as requiring human intelligence. Artificial intelligence, as this goal is known, actually predates the first electronic computers in the 1940s, although the term was not coined until 1956.

Magnetic storage media

Computer graphics was introduced in the early 1950s with the display of data or crude images on paper plots and cathode-ray tube (CRT) screens. Expensive hardware and the limited availability of software kept the field from growing until the early 1980s, when the computer memory required for bit-map graphics became affordable. (A bit map is a binary representation in main memory of the rectangular array of points [pixels, or picture elements] on the screen. Because the first bit-map displays used one binary bit per pixel, they were capable of displaying only one of two colours, commonly black and green or black and amber. Later computers, with more memory, assigned more binary bits per pixel to obtain more colours.) Bit-map technology, together with high-resolution display screens and the development of graphics standards that make software less machine-dependent, has led to the explosive growth of the field. Software engineering arose as a distinct area of study in the late 1970s as part of an attempt to introduce discipline and structure into the software design and development process. For a thorough discussion of the development of computing, see COMPUTERS.

Architecture

Architecture deals with both the design of computer components (hardware) and the creation of operating systems (software) to control the computer. Although designing and building computers is often considered the province of computer engineering, in practice there exists considerable overlap with computer science.

BASIC COMPUTER COMPONENTS

A digital computer typically consists of a control unit, an arithmetic-logic unit, a memory unit, and input/output units, as illustrated in Figure 1. The arithmetic-logic unit

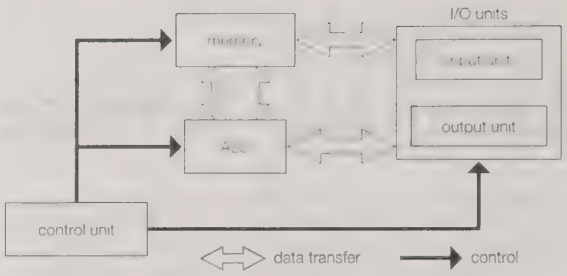

Figure 1: The basic organization of a computer.

(ALU) performs simple addition, subtraction, multiplication, division, and logic operations—such as OR and AND. The main computer memory, usually high-speed random-access memory (RAM), stores instructions and data. The control unit fetches data and instructions from memory and effects the operations of the ALU. The control unit and ALU usually are referred to as a processor, or central processing unit (CPU). The operational speed of the CPU primarily determines the speed of the computer as a whole. The basic operation of the CPU is analogous to a computation carried out by a person using an arithmetic calculator, as illustrated in Figure 2. The control unit corresponds to the human brain and the memory to a notebook that stores the program, initial data, and intermediate and final computational results. In the case of an electronic computer, the CPU and fast memories are realized with transistor circuits.

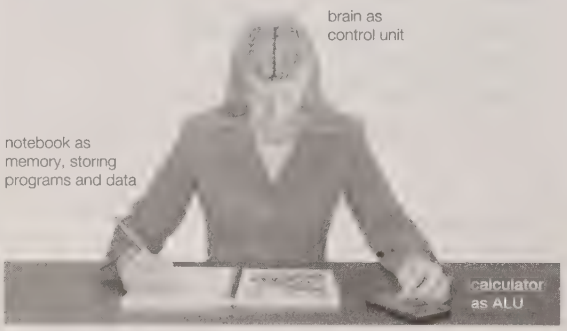

Figure 2: *Basic operation of the central processing unit.* The CPU functions in much the way a person does when carrying out an arithmetic computation using a calculator.

I/O units, or devices, are commonly referred to as computer peripherals and consist of input units (such as keyboards and optical scanners) for feeding instructions and data into the computer and output units (such as printers and monitors) for displaying results.

In addition to RAM, a computer usually contains some slower, but larger and permanent, secondary memory storage. Almost all computers contain a magnetic storage device known as a hard disk, as well as a disk drive to read from or write to removable magnetic media known as floppy disks. Various optical and magnetic-optical hybrid removable storage media are also quite common, such as CD-ROMs (compact disc read-only memory) and DVD-ROMs (digital video [or versatile] disc read-only memory).

Computers also often contain a cache—a small, extremely fast (compared with RAM) memory unit that can store information that will be urgently or frequently needed. Current research includes cache design and algorithms that can predict what data is likely to be needed next and preload it into the cache for improved performance.

BASIC COMPUTER OPERATION

The operation of such a computer, once a program and some data have been loaded into RAM, is as follows. The first instruction is transferred from RAM into the control unit and interpreted by the hardware circuitry. For instance, suppose that the instruction is a string of bits that is the code for LOAD 10. This instruction loads the contents of memory location 10 into the ALU. The next in-

struction—say, ADD 15—is fetched. The control unit then loads the contents of memory location 15 into the ALU and adds it to the number already there. Finally, the instruction STORE 20 would store the sum in location 20. At this level the operation of a computer is not much different from that of a pocket calculator. In general, of course, programs are not just lengthy sequences of LOAD, STORE, and arithmetic operations. Most importantly, computer languages include conditional instructions, essentially rules that say, "If memory location *n* satisfies condition *a*, do instruction number *x* next, otherwise do instruction *y*." This allows the course of a program to be determined by the results of previous operations—a critically important ability.

LOGIC DESIGN AND INTEGRATED CIRCUITS

Logic design is the area of computer science that deals with the design of electronic circuits to carry out the operations of the control unit, the ALU, the I/O controllers, and more. For example, the addition circuit of the ALU has inputs corresponding to all the bits of the two numbers to be added and outputs corresponding to the bits of the sum. The arrangement of wires and transistors that link inputs to outputs is determined by logic-design principles. The design of the control unit provides the circuits that interpret instructions and control subsequent behaviour. Clearly, it is critical that this circuitry be as efficient as possible; logic design deals with optimizing the circuitry, not just putting together something that will work. Boolean algebra is the mathematical tool used for logic design.

An important area related to architecture is the design of computer chips, or microprocessors, a type of integrated circuit. A microprocessor is a complete CPU—control unit, ALU, and possibly some memory (especially cache)—on a single integrated circuit chip. Additional memory and I/O control circuitry are linked to this chip to form a complete computer. These thumbnail-sized devices contain thousands or millions of transistors, together with wiring, to form the processing and memory units of modern computers.

VLSI circuit design

The process of very-large-scale integrated (VLSI) circuit design involves a number of stages, which characteristically are as follows: (1) creating the initial functional or behavioral specification, (2) encoding this specification into a hardware description language, (3) breaking down the design into modules and generating sizes and shapes for the eventual chip components, and (4) chip planning, which includes building a "floor plan" to indicate where on the chip the components are to be placed and how they are to be interconnected. The modularization, sizing, and planning stages are often iterated before a final design is reached. The final stage is the formulation of the instructions for the automated production of the chip through an optical lithography process. Computer scientists are involved not only in creating the computer-aided design (CAD) tools to support engineers in the various stages of chip design but also in providing the necessary theoretical results, such as how to efficiently design a floor plan with near-minimal area that satisfies the given constraints.

Advances in integrated-circuit technology have been incredible. For example, in 1971 the first microprocessor chip (Intel Corporation's 4004) had only 2,300 transistors, in 1993 Intel's Pentium chip had more than 3 million transistors, and in 2000 Intel's Pentium 4 contained about 42 million transistors. Meanwhile, memory chips reached a billion transistors per chip before 1999.

As the growth of the personal computer industry in the 1980s and '90s fueled research into ever more powerful processors at ever lower costs, microprocessors became ubiquitous—controlling automated assembly lines, traffic signal systems, and retail inventory systems, to name a few applications, and being embedded in many consumer products, such as automobile fuel-injection systems, kitchen appliances, audio systems, cell phones, and electronic games.

Embedded microprocessors

LINKING PROCESSORS

Multiprocessor design. Creating a multiprocessor from a number of uniprocessors (one CPU) requires physical links and a mechanism for communication among the processors so that they may operate in parallel. Tightly coupled multiprocessors share memory and hence may communicate by storing information in memory accessible by all processors. Loosely coupled multiprocessors, including computer networks, communicate by sending messages to each other across the physical links. Computer scientists investigate various aspects of such multiprocessor architectures. For example, the possible geometric configurations in which hundreds or even thousands of processors may be linked together are examined to find the geometry that best supports computations. A much studied topology is the hypercube, in which each processor is connected directly to some fixed number of neighbours: two for the two-dimensional square, three for the three-dimensional cube, and similarly for the higher dimensional hypercubes. Computer scientists also investigate methods for carrying out computations on such multiprocessor machines—*e.g.*, algorithms to make optimal use of the architecture, measures to avoid conflicts as data and instructions are transmitted among processors, and so forth. The machine-resident software that makes possible the use of a particular machine, in particular its operating system (see below *Software: Operating systems*), is in many ways an integral part of its architecture.

Network protocols. Another important architectural area is the computer communications network, in which computers are linked together via computer cables, infrared light signals, or low-power radiowave transmissions over short distances to form local area networks (LANs) or via telephone lines, television cables, or satellite links to form wide-area networks (WANs). By the 1990s, the Internet, a network of networks, made it feasible for nearly all computers in the world to communicate. Linking computers physically is easy; the challenge for computer scientists has been the development of protocols—standardized rules for the format and exchange of messages—to allow processes running on host computers to interpret the signals they receive and to engage in meaningful "conversations" in order to accomplish tasks on behalf of users. Network protocols also include flow control, which keeps a data sender from swamping a receiver with messages it has no time to process or space to store, and error control, which involves error detection and automatic resending of messages to compensate for errors in transmission. For some of the technical details of error detection and error correction, see INFORMATION THEORY.

The standardization of protocols has been an international effort for many years. Since it would otherwise be impossible for different kinds of machines running diverse operating systems to communicate with one another, the key concern has been that system components (computers) be "open"—*i.e.*, open for communication with other open components. This terminology comes from the open systems interconnection (OSI) communication standards, established by the International Organization for Standardization. The OSI reference model specifies protocol standards in seven "layers." The layering provides a modularization of the protocols and hence of their implementations. Each layer is defined by the functions it relies upon from the next lower level and by the services it provides to the layer above it. At the lowest level, the physical layer, rules for the transport of bits across a physical link are defined. Next, the data-link layer handles standard-size "packets" of data bits and adds reliability in the form of error detection and flow control. Network and transport layers (often combined in implementations) break up messages into the standard-size packets and route them to their destinations. The session layer supports interactions between application processes on two hosts (machines). For example, it provides a mechanism with which to insert checkpoints (saving the current status of a task) into a long file transfer so that, in case of a failure, only the data after the last checkpoint need to be retransmitted. The presentation layer is concerned with such functions as transformation of data encodings, so that heterogeneous systems may engage in meaningful communication. At the highest, or application, level are protocols that support specific applications. An example of such an

The OSI reference model

application is the transfer of files from one host to another. Another application allows a user working at any kind of terminal or workstation to access any host as if the user were local.

Distributed computing. The building of networks and the establishment of communication protocols have led to distributed systems, in which computers linked in a network cooperate on tasks. A distributed database system, for example, consists of databases residing on different network sites. Data may be deliberately replicated on several different computers for enhanced availability and reliability, or the linkage of computers on which databases already reside may accidentally cause an enterprise to find itself with distributed data. Software that provides coherent access to such distributed data then forms a distributed database management system.

Client-server architecture. The client-server architecture has become important in designing systems that reside on a network. In a client-server system, one or more clients (processes) and one or more servers (also processes, such as database managers or accounting systems) reside on various host sites of a network. Client-server communication is supported by facilities for interprocess communication both within and between hosts. Clients and servers together allow for distributed computation and presentation of results. Clients interact with users, providing an interface to allow the user to request services of the server and to display the results from the server. Clients usually do some interpretation or translation, formulating commands entered by the user into the formats required by the server. Clients may provide system security by verifying the identity and authorization of the users before forwarding their commands. Clients may also check the validity and integrity of user commands; for example, they may restrict bank account transfers to certain maximum amounts. In contrast, servers never initiate communications; instead they wait to respond to requests from clients. Ideally, a server should provide a standardized interface to clients that is transparent—*i.e.,* an interface that does not require clients to be aware of the specifics of the server system (hardware and software) that is providing the service. In today's environment, in which local area networks are common, the client-server architecture is very attractive. Clients are made available on individual workstations or personal computers, while servers are located elsewhere on the network, usually on more powerful machines. In some discussions the machines on which client and server processes reside are themselves referred to as clients and servers.

Middleware. A major disadvantage of using a pure client-server approach to system design is that clients and servers must be designed together. That is, in order to work with a particular server application, the client must be using compatible software. One common solution to this difficulty is the three-tier client-server architecture, in which a middle tier, known as middleware, is placed between the server and the clients to handle the translations necessary for different client platforms. Middleware also works in the other direction, allowing clients easy access to an assortment of applications on heterogeneous servers. For example, middleware could allow a company's sales force to access data from several different databases and to interact with customers who are using different types of computers.

Web servers. The other major approach to client-server communications is via the World Wide Web. Web servers may be accessed over the Internet from almost any hardware platform with client applications known as Web browsers. In this architecture, clients need few capabilities beyond Web browsing (the simplest such clients are known as network machines and are analogous to simple computer terminals). This is because the Web server can hold all of the desired applications and handle all of the requisite computations, with the client's role limited to supplying input and displaying the server-generated output. This approach to the implementation of, for example, business systems for large enterprises with hundreds or even thousands of clients is likely to become increasingly common in the future.

RELIABILITY

Reliability is an important issue in systems architecture. Components may be replicated to enhance reliability and increase availability of the system functions. Such applications as aircraft control and manufacturing process control are likely to run on systems with backup processors ready to take over if the main processor fails, often running in parallel so the transition to the backup is smooth. If errors are potentially disastrous, as in aircraft control, results may be collected from replicated processes running in parallel on separate machines and disagreements settled by a voting mechanism. Computer scientists are involved in the analysis of such replicated systems, providing theoretical approaches to estimating the reliability achieved by a given configuration and processor parameters, such as average time between failures and average time required to repair the processor. Reliability is also an issue in distributed systems. For example, one of the touted advantages of a distributed database is that data replicated on different network hosts are more available, so applications that require the data will execute more reliably.

Replication

REAL-TIME SYSTEMS

The design of real-time systems is becoming increasingly important. Computers have been incorporated into cars, aircraft, manufacturing assembly lines, and other applications to control processes as they occur—known as "in real time." It is not practical in such instances to provide input to the computer, allow it to compute for some indefinite length of time, and then examine the output. The computer output must be available in a timely fashion, and the processor (or processors) must be carefully chosen and the tasks specially scheduled so that deadlines are met. Frequently, real-time tasks repeat at fixed time intervals; for example, every so many seconds, sensor data are gathered and analyzed and a control signal generated. In such cases, scheduling theory is utilized by the systems designer in determining how the tasks should be scheduled on a given processor. A good example of a system that requires real-time action is the antilock braking system (ABS) on most newer vehicles; because it is critical that the ABS instantly react to brake-pedal pressure and begin a program of pumping the brakes, such an application is said to have a hard deadline. Some other real-time systems are said to have soft deadlines, in that, although it is deemed important to meet them, no disaster will happen if the system's response is slightly delayed; an example is ocean shipping and tracking systems. The concept of "best effort" arises in real-time system design, not only because soft deadlines may sometimes be slipped, but because hard deadlines may sometimes be met by computing a less than optimal result. For example, most details on an air traffic controller's screen are approximations—*e.g.,* altitude, which need not be displayed to the nearest inch—that do not interfere with air safety.

Scheduling theory

Software

SOFTWARE ENGINEERING

Computer programs, the software that is becoming an ever-larger part of the computer system, are growing more and more complicated, requiring teams of programmers and years of effort to develop. As a consequence, a new subdiscipline, software engineering, has arisen. The development of a large piece of software is perceived as an engineering task, to be approached with the same care as the construction of a skyscraper, for example, and with the same attention to cost, reliability, and maintainability of the final product. The software-engineering process is usually described as consisting of several phases, variously defined but in general consisting of: (1) identification and analysis of user requirements, (2) development of system specifications (both hardware and software), (3) software design (perhaps at several successively more detailed levels), (4) implementation (actual coding), (5) testing, and (6) maintenance.

Even with such an engineering discipline in place, the software-development process is expensive and time-consuming. Since the early 1980s, increasingly sophisticated

tools have been built to aid the software developer and to automate as much as possible the development process. Such computer-aided software engineering (CASE) tools span a wide range of types, from those that carry out the task of routine coding when given an appropriately detailed design in some specification language to those that incorporate an expert system to enforce design rules and eliminate software defects prior to the coding phase.

CASE

As the size and complexity of software has grown, the concept of reuse has become increasingly important in software engineering, since it is clear that extensive new software cannot be created cheaply and rapidly without incorporating existing program modules (subroutines, or pieces of computer code). One of the attractive aspects of object-oriented programming is that code written in terms of objects is readily reused. As with other aspects of computer systems, reliability—usually rather vaguely defined as the likelihood of a system to operate correctly over a reasonably long period of time—is a key goal of the finished software product. Sophisticated techniques for testing software have therefore been designed. For example, a large software product might be deliberately "seeded" with artificial faults, or "bugs"; if they are all discovered through testing, there is a high probability that most actual faults likely to cause computational errors have been discovered as well. The need for better-trained software engineers has led to the development of educational programs in which software engineering is either a specialization within computer science or a separate program. The recommendation that software engineers, like other engineers, be licensed or certified is gaining increasing support, and there is momentum toward the accreditation of software engineering degree programs.

PROGRAMMING LANGUAGES

Early languages. Programming languages are the languages in which a programmer writes the instructions that the computer will ultimately execute. The earliest programming languages were assembly languages, not far removed from the binary-encoded instructions directly executed by the machine hardware. Users soon (beginning in the mid-1950s) invented more convenient languages.

FORTRAN. The early language FORTRAN (Formula Translator) was originally much like assembly language; however, it allowed programmers to write algebraic expressions instead of coded instructions for arithmetic operations. As learning to program computers became increasingly important in the 1960s, a stripped-down "basic" version of FORTRAN called BASIC (Beginner's All-Purpose Symbolic Instruction Code) was written by John G. Kemeny and Thomas E. Kurtz at Dartmouth College, Hanover, N.H., U.S., to teach novices simple programming skills. BASIC quickly spread to other academic institutions, and, beginning about 1980, versions of BASIC for personal computers allowed even students at elementary schools to learn the fundamentals of programming.

COBOL. At roughly the same time that FORTRAN was created, COBOL (Common Business-Oriented Language) was developed to handle records and files and the operations necessary for simple business applications. The trend since then has been toward developing increasingly abstract languages, allowing the programmer to think and communicate with the machine at a level ever more remote from machine code.

Imperative versus functional languages. COBOL, FORTRAN, and their descendants, such as Pascal and C, are known as imperative languages, since they specify as a sequence of explicit commands how the machine is to go about solving the problem at hand; this is not very different from what takes place at the machine level. Other languages are functional, in the sense that programming is done by calling (*i.e.,* invoking) functions or procedures, which are sections of code executed within a program. The best-known language of this type is LISP (List Processing), in which all computation is expressed as an application of a function to one or more "objects." Since LISP objects may be other functions as well as individual data items (variables, in mathematical terminology) or data structures (see below *Theory: Data structures and algorithms*), a programmer can create functions at the appropriate level of abstraction to solve the problem at hand. This feature has made LISP a popular language for artificial intelligence applications, although it has been somewhat superseded by logic programming languages such as Prolog (Programming in Logic). These are termed nonprocedural, or declarative, languages in the sense that the programmer specifies what goals are to be accomplished but not how specific methods are to be applied to attain those goals. Prolog is based on the concepts of resolution (akin to logical deduction) and unification (similar to pattern matching). Programs in such languages are written as a sequence of goals. A recent extension of logic programming is constraint logic programming, in which pattern matching is replaced by the more general operation of constraint satisfaction. Again, programs are a sequence of goals to be attained, in this case the satisfaction of the specified constraints.

LISP

Recent developments. *Object-oriented languages.* An important trend in programming languages is support for data encapsulation, or object-oriented code. Data encapsulation is best illustrated by the language Smalltalk, in which all programming is done in terms of so-called objects. An object in Smalltalk or similar object-oriented languages consists of data together with the procedures (program segments) to operate on that data. Encapsulation refers to the fact that an object's data can be accessed only through the methods (procedures) provided. Programming is done by creating objects that send messages to one another so that tasks can be accomplished cooperatively by invoking each others' methods. This object-oriented paradigm has been very influential. For example, the language C, which was popular for engineering applications and systems development, has largely been supplanted by its object-oriented extension C++. An object-oriented version of BASIC, named Visual BASIC, is available for personal computers and allows even novice programmers to create interactive applications with elegant graphical user interfaces (GUIs).

In 1995 Sun Microsystems, Inc., introduced Java, yet another object-oriented language. Applications written in Java are not translated into a particular machine language but into an intermediate language called Java Bytecode, which may be executed on any computer (such as those using UNIX, Macintosh, or Windows operating systems) with a Java interpretation program known as a Java virtual machine. Thus Java is ideal for creating distributed applications or Web-based applications. The applications can reside on a server in Bytecode form, which is readily downloaded to and executed on any Java virtual machine. In many cases it is not desirable to download an entire application but only an interface through which a client may communicate interactively with the application. Java applets (small chunks of application code) solve this problem. Residing on Web-based servers, they may be downloaded to and run in any standard Web browser to provide, for example, a client interface to a game or database residing on a server.

Java

Concurrency. Concurrency refers to the execution of more than one procedure at the same time (perhaps with the access of shared data), either truly simultaneously (as on a multiprocessor) or in an unpredictably interleaved manner. Languages such as Ada (the U.S. Department of Defense standard applications language from 1983 until 1997) include both encapsulation and features to allow the programmer to specify the rules for interactions between concurrent procedures or tasks.

High-level languages. At a still higher level of abstraction lie visual programming languages, in which programmers graphically express what they want done by means of icons to represent data objects or processes and arrows to represent data flow or sequencing of operations. As of yet, none of these visual programming languages has found wide commercial acceptance. On the other hand, high-level user-interface languages for special-purpose software have been much more successful; for example, languages like Mathematica, in which sophisticated mathematics may be easily expressed, or the "fourth generation" database-querying languages that allow users to express requests for

data with simple English-like commands. For example, a query such as "Select salary from payroll where employee = 'Jones,' " written in the database language SQL (Structured Query Language), is easily understood by the reader.

HTML

The high-level language HTML (HyperText Markup Language) allows nonprogrammers to design Web pages by specifying their structure and content but leaves the detailed presentation and extraction of information to the client's Web browser.

Program translation. Computer programs written in any language other than machine language must be either interpreted or compiled. An interpreter is software that examines a computer program one instruction at a time and calls on code to execute the operations required by that instruction. This is a rather slow process. A compiler is software that translates a computer program as a whole into machine code that is saved for subsequent execution whenever desired. Much work has been done on making both the compilation process and the compiled code as efficient as possible. When a new language is developed, it is usually at first interpreted. If the language becomes popular, it

Compilers

becomes important to write compilers for it, although this may be a task of considerable difficulty. There is an intermediate approach, which is to compile code not into machine language but into an intermediate language that is close enough to machine language that it is efficient to interpret—though not so close that it is tied to the machine language of a particular computer. It is use of this approach that provides the Java language with its computer-platform independence.

OPERATING SYSTEMS

Development of operating systems. In early computers, the user typed programs onto punched tape or cards, from which they were read into the computer. The computer subsequently assembled or compiled the programs and then executed them, and the results were then transmitted to a printer. It soon became evident that much valuable computer time was wasted between users and also while jobs (programs to be executed) were being read or while the results were being printed. The earliest operating systems consisted of software residing in the computer that handled "batches" of user jobs—*i.e.,* sequences of jobs stored on magnetic tape that are read into computer memory and executed one at a time without intervention by user or operator. Accompanying each job in a batch were instructions to the operating system (OS) detailing the resources needed by the job—for example, the amount of CPU time, the files and the storage devices on which they resided, the output device, whether the job consisted of a program that needed to be compiled before execution, and so forth. From these beginnings came the key concept of an operating system as a resource allocator. This role became more important with the rise of multiprogramming, in which several jobs reside in the computer simultaneously and share resources—for example, being allocated fixed amounts of CPU time in turn. More sophisticated hardware allowed one job to be reading data while another wrote to a printer and still another performed computations. The operating system was the software that managed these tasks in such a way that all the jobs were completed without interfering with one another.

Further work was required of the operating system with the advent of interactive computing, in which the user enters commands directly at a terminal and waits for the system to respond. Processes known as terminal handlers were added to the system, along with mechanisms like interrupts (to get the attention of the operating system to handle urgent tasks) and buffers (for temporary storage of data during input/output to make the transfer run more smoothly). A large computer can now interact with hundreds of users simultaneously, giving each the perception of being the sole user. The first personal computers used relatively simple operating systems, such as some variant

DOS

of DOS (disk operating system), with the main jobs of managing the user's files, providing access to other software (such as word processors), and supporting keyboard input and screen display. Perhaps the most important trend in operating systems today is that they are becoming increasingly machine-independent. Hence, users of modern, portable operating systems like UNIX, Microsoft Corporation's Windows NT, and Linux are not compelled to learn a new operating system each time they purchase a new, faster computer (possibly using a completely different processor).

Deadlock and synchronization. Among the problems that need to be addressed by computer scientists in order for sophisticated operating systems to be built are deadlock and process synchronization. Deadlock occurs when two or more processes (programs in execution) request the same resources and are allocated them in such a way that a circular chain of processes is formed, where each process is waiting for a resource held by the next process in the chain. As a result, no process can continue; they are deadlocked. An operating system can handle this situation with various prevention or detection and recovery techniques. For example, resources might be numbered 1, 2, 3, and so on. If they must be requested by each process in this order, it is impossible for a circular chain of deadlocked processes to develop. Another approach is simply to allow deadlocks to occur, detect them by examining nonactive processes and the resources they are holding, and break any deadlock by aborting one of the processes in the chain and releasing its resources.

Process synchronization is required when one process must wait for another to complete some operation before proceeding. For example, one process (called a writer) may be writing data to a certain main memory area, while another process (a reader) may be reading data from that area and sending it to the printer. The reader and writer must be synchronized so that the writer does not overwrite existing data with new data until the reader has processed it. Similarly, the reader should not start to read until data has actually been written to the area. Various synchronization techniques have been developed. In one method, the operating system provides special commands that allow one process to signal to the second when it begins and completes its operations, so that the second knows when it may start. In another approach, shared data, along with the code to read or write them, are encapsulated in a protected program module. The operating system then enforces rules of mutual exclusion, which allow only one reader or writer at a time to access the module. Process synchronization may also be supported by an interprocess communication facility, a feature of the operating system that allows processes to send messages to one another.

Designing software as a group of cooperating processes has been made simpler by the concept of "threads." A single process may contain several executable programs (threads) that work together as a coherent whole. One thread might, for example, handle error signals, another might send a message about the error to the user, while a third thread is executing the actual task of the process. Modern operating systems provide management services (*e.g.,* scheduling, synchronization) for such multithreaded processes.

Threads

Virtual memory. Another area of operating-system research has been the design of virtual memory. Virtual memory is a scheme that gives users the illusion of working with a large block of contiguous memory space (perhaps even larger than real memory), when in actuality most of their work is on auxiliary storage (disk). Fixed-size blocks (pages) or variable-size blocks (segments) of the job are read into main memory as needed. Questions such as how much actual main memory space to allocate to users and which page to return to disk ("swap out") to make room for an incoming page must be addressed in order for the system to execute jobs efficiently. Some virtual memory issues must be continually reexamined; for example, the optimal page size may change as main memory becomes larger and quicker.

Job scheduling. The allocation of system resources to various tasks, known as job scheduling, is a major assignment of the operating system. The system maintains prioritized queues of jobs waiting for CPU time and must decide which job to take from which queue and how much time to allocate to it, so that all jobs are completed in a fair and timely manner.

Graphical user interfaces. A highly visible aspect of the change in operating systems in recent years is the increasingly prevalent use of graphical user interfaces (GUIs). In the early days of computing, punch cards, written in the Job Control Language (JCL), were used to specify precisely which system resources a job would need and when the operating system should assign them to the job. Later, computer consoles allowed an operator directly to type commands—*e.g.,* to open files, run programs, manipulate data, and print results—that could be executed immediately or at some future time. (Operating system commands stored for later execution are generally referred to as scripts; scripts are still widely used, especially for controlling servers.) With the advent of personal computers and the desire to make them more user-friendly, the operating system interface has become for most users a set of icons and menus so that the user only needs to "point and click" to send a command to the operating system.

Scripts

Distributed operating systems. With the advent of computer networks, in which many computers are linked together and are able to communicate with one another, distributed computing became feasible. A distributed computation is one that is carried out on more than one machine in a cooperative manner. A group of linked computers working cooperatively on tasks, referred to as a distributed system, often requires a distributed operating system to manage the distributed resources. Distributed operating systems must handle all the usual problems of operating systems, such as deadlock. Distributed deadlock is very difficult to prevent; it is not feasible to number all the resources in a distributed system. Hence, deadlock must be detected by some scheme that incorporates substantial communication among network sites and careful synchronization, lest network delays cause deadlocks to be falsely detected and processes aborted unnecessarily. Interprocess communication must be extended to processes residing on different network hosts, since the loosely coupled architecture of computer networks requires that all communication be done by message passing. Important systems concerns unique to the distributed case are workload sharing, which attempts to take advantage of access to multiple computers to complete jobs faster; task migration, which supports workload sharing by efficiently moving jobs among machines; and automatic task replication at different sites for greater reliability. These concerns, in addition to the overall design of distributed operating systems and their interaction with the operating systems of the component computers, are subjects of current research.

INFORMATION SYSTEMS AND DATABASES

File storage. Computers have been used since the 1950s for the storage and processing of data. An important point to note is that the main memory of a computer provides only temporary storage; any data stored in main memory is lost when the power is turned off. For the permanent storage of data, one must turn to auxiliary storage, primarily magnetic and optical media such as tapes, disks, and CDs. Data is stored on such media but must be read into main memory for processing. A major goal of information-system designers has been to develop software to locate specific data on auxiliary storage and read it efficiently into main memory for processing. The underlying structure of an information system is a set of files stored permanently on some secondary storage device. The software that comprises a file management system supports the logical breakdown of a file into records. Each record describes some thing (or entity) and consists of a number of fields, where each field gives the value of some property (or attribute) of the entity. A simple file of records is adequate for uncomplicated business data, such as an inventory of a grocery store or a collection of customer accounts.

Early file systems were always sequential, meaning that the successive records had to be processed in the order in which they were stored, starting from the beginning and proceeding down to the end. This file structure was appropriate and was in fact the only one possible when files were stored solely on large reels of magnetic tape and skipping around to access random data was not feasible. Sequential files are generally stored in some sorted order (*e.g.,* alphabetic) for printing of reports (*e.g.,* a telephone directory) and for efficient processing of batches of transactions. Banking transactions (deposits and withdrawals), for instance, might be sorted in the same order as the accounts file, so that as each transaction is read the system need only scan ahead (never backward) to find the accounts record to which it applies.

When so-called direct-access storage devices (primarily magnetic disks) were developed, it became possible to access a random data block on the disk. (A data block is the unit of transfer between main memory and auxiliary storage and usually consists of several records.) Files can then be indexed so that an arbitrary record can be located and fetched (loaded into the main memory). An index of a file is much like an index of a book; it consists of a listing of identifiers that distinguish the records (*e.g.,* names might be used to identify personnel records), along with the records' locations. Since indexes might be long, they are usually structured in some hierarchical fashion and are navigated by using pointers, which are identifiers that contain the address (location in memory) of some item. The top level of an index, for example, might contain locations of (point to) indexes to items beginning with the letters *A, B,* etc. The *A* index itself may contain not locations of data items but pointers to indexes of items beginning with the letters *Ab, Ac,* and so on. Reaching the final pointer to the desired record by traversing such a treelike structure is quite rapid. File systems making use of indexes can be either purely indexed, in which case the records need be in no particular order and every individual record must have an index entry that points to the record's location, or they can be "indexed-sequential." In this case a sort order of the records as well as of the indexes is maintained, and index entries need only give the location of a block of sequentially ordered records. Searching for a particular record in a file is aided by maintaining secondary indexes on arbitrary attributes as well as by maintaining a primary index on the same attribute on which the file is sorted. For example, a personnel file might be sorted on (and maintain a primary index on) employee identification numbers, but it might also maintain indexes on names and departments. An indexed-sequential file system supports not only file search and manipulation commands of both a sequential and index-based nature but also the automatic creation of indexes.

Random access

Types of database models. File systems of varying degrees of sophistication satisfied the need for information storage and processing for several years. However, large enterprises tended to build many independent files containing related and even overlapping data, and data-processing activities frequently required the linking of data from several files. It was natural, then, to design data structures and database management systems that supported the automatic linkage of files. Three database models were developed to support the linkage of records of different types. These are: (1) the hierarchical model, in which record types are linked in a treelike structure (*e.g.,* employee records might be grouped under a record describing the departments in which employees work); (2) the network model, in which arbitrary linkages of record types may be created (*e.g.,* employee records might be linked both to employees' departments and to their supervisors—that is, other employees); and (3) the relational model, in which all data are represented in simple tabular form.

In the relational model, the description of a particular entity is provided by the set of its attribute values, stored as one row of the table, or relation. This linkage of n attribute values to provide a meaningful description of a real-world entity or a relationship among such entities forms a mathematical n-tuple; in database terminology, it is simply called a *tuple.* The relational approach also supports queries that involve several tables, providing automatic linkage across tables by means of a "join" operation that combines records with identical values of common attributes. Payroll data, for example, could be stored in one table and personnel benefits data in another; complete information on an employee could be obtained by joining the tables on the employee's identification number. To support any of these database structures, a large piece of software known as a database management system (DBMS) is required to han-

DBMS

dle the storage and retrieval of data (via the file management system, since the data are stored as files on magnetic disk) and to provide the user with commands to query and update the database. The relational approach is currently the most popular, as older hierarchical data management systems, such as IMS, the information management system produced by IBM, are replaced by relational database management systems such as IBM's large mainframe system DB2 or the Oracle Corporation's DBMS, which runs on large servers. Relational DBMS software is also available for workstations and personal computers.

The need for more powerful and flexible data models to support scientific and engineering applications has led to extended relational data models in which table entries need not be simple values but can be programs, text, unstructured data in the form of binary large objects, or any other format the user requires. Another development has been the incorporation of the object concept that has become significant in programming languages. In object-oriented databases, all data are objects. Objects may be linked together by an "is-part-of" relationship to represent larger, composite objects. Data describing a truck, for instance, may be stored as a composite of a particular engine, chassis, drive train, and so forth. Classes of objects may form a hierarchy in which individual objects may inherit properties from objects farther up in the hierarchy. For example, objects of the class "motorized vehicle" all have an engine; members of subclasses such as "truck" or "airplane" will then also have an engine. Furthermore, engines are also data objects, and the engine attribute of a particular vehicle will be a link to a specific engine object. Multimedia databases, in which voice, music, and video are stored along with the traditional textual information, are becoming increasingly important and also are providing an impetus toward viewing data as objects, as are databases of pictorial images such as photographs or maps. The future of database technology is generally perceived to be a merging of the relational and object-oriented views.

Object-oriented database

Data integrity. Integrity is a major database issue. In general, integrity refers to maintaining the correctness and consistency of the data. Some integrity checking is made possible by specifying the data type of an item. For example, if an identification number is specified to be nine digits, the DBMS may reject an update attempting to assign a value with more or fewer digits or one including an alphabetic character. Another type of integrity, known as referential integrity, requires that an entity referenced by the data for some other entity must itself exist in the database. For example, if an airline reservation is requested for a particular flight number, then the flight referenced by that number must actually exist. Although one could imagine integrity constraints that limit the values of data items to specified ranges (to prevent the famous "computer errors" of the type in which a $10 check is accidentally issued as $10,000), most database management systems do not support such constraints but leave them to the domain of the application program.

Access to a database by multiple simultaneous users requires that the DBMS include a concurrency control mechanism to maintain the consistency of the data. For example, two travel agents may try to book the last seat on a plane at more or less the same time. Without concurrency control, both may think they have succeeded, while only one booking is actually entered into the database. A key concept in concurrency control is the transaction, defined as a sequence of operations on the data that transform the database from one consistent state into another. Consider the simple example of an electronic transfer of funds (say, $5) from bank account A to account B. Deducting $5 from account A leaves the database inconsistent in that the total over all accounts is $5 short. Similarly, adding $5 to account B in itself makes the total $5 too much. Combining these two operations, however, yields a valid transaction. The key to maintaining a correct database is to ensure that only complete transactions are applied to the data and that multiple concurrent transactions are executed (under a concurrency control mechanism) in such a way that a serial order can be defined that would produce the same results. A transaction-oriented control mechanism for database access becomes difficult in the case of so-called long transactions—for example, when several engineers are working, perhaps over the course of several days, on a product design that may not reach a consistent state until the project is complete. The best approach to handling long transactions is a current area of database research.

As discussed above, databases may be distributed, in the sense that data reside at different host computers on a network. Distributed data may or may not be replicated, but in any case the concurrency-control problem is magnified. Distributed databases must have a distributed database management system to provide overall control of queries and updates, ideally without requiring that the user know the location of the data. The attainment of the ideal situation, in which various databases fall under the unified control of a distributed DBMS, has been slowed both by technical problems and by such practical problems as heterogeneous hardware and software and database owners who desire local autonomy. Increasing mention is being made of more loosely linked collections of data, known by such names as multidatabases or federated databases. A closely related concept is interoperability, the ability of the user of one member of a group of disparate systems (all with the same functionality) to work with any of the systems of the group with equal ease and via the same interface. In the case of database management systems, interoperability means the ability of users to formulate queries to any one of a group of independent, autonomous database management systems using the same language, to be provided with a unified view of the contents of all the individual databases, to formulate queries that may require fetching data via more than one of the systems, and to be able to update data stored under any member of the group. Many of the problems of distributed databases are the problems of distributed systems in general. Thus distributed databases may be designed as client-server systems, with middleware easing the heterogeneity problems.

Federated database

Database security. Security is another important database issue. Data residing on a computer is under threat of being stolen, destroyed, or modified maliciously. This is true whenever the computer is accessible to multiple users but is particularly significant when the computer is accessible over a network. The first line of defense is to allow access to a computer only to authorized users and to authenticate those users by a password or similar mechanism. But clever programmers have learned how to evade such mechanisms, designing, for example, so-called computer viruses—programs that replicate themselves and spread among the computers in a network, "infecting" systems and potentially destroying files. Data can be stolen by devices such as "Trojan horses"—programs that carry out some useful task but contain hidden malicious code—or by simply eavesdropping on network communications. The need to protect sensitive data has led to extensive research in cryptography and the development of encryption standards for providing a high level of confidence that the data is safe from decoding by even the most powerful computer attacks. The term *computer theft,* however, usually refers not to theft of information from a computer but rather to theft by use of a computer, typically by modifying data. If a bank's records are not adequately secure, for example, someone could set up a false account and transfer money into it from valid accounts for later withdrawal.

Computer virus

ARTIFICIAL INTELLIGENCE

Artificial intelligence (AI) is an area of research that goes back to the very beginnings of computer science. The idea of building a machine that can perform tasks perceived as requiring human intelligence is an attractive one. The tasks that have been studied from this point of view include game playing, language translation, natural-language understanding, fault diagnosis, robotics, and supplying expert advice. For a detailed discussion of the successes—and failures—of AI over the years, see ARTIFICIAL INTELLIGENCE.

COMPUTER GRAPHICS

Computer graphics is the field that deals with display and control of images on the computer screen. Applications may be broken down into four major categories: (1) design

CAD

(computer-aided design [CAD] systems), in which the computer is used as a tool in designing objects ranging from automobiles to bridges to computer chips by providing an interactive drawing tool and an interface to simulation and analysis tools for the engineer; (2) fine arts, in which artists use the computer screen as a medium to create images of impressive beauty, cinematographic special effects, animated cartoons, and television commercials; (3) scientific visualization, in which simulations of scientific events—such as the birth of a star or the development of a tornado—are exhibited pictorially and in motion so as to provide far more insight into the phenomena than would tables of numbers; and (4) human-computer interfaces.

Graphics-based computer interfaces, which enable users to communicate with the computer by such simple means as pointing to an icon with a handheld device known as a mouse, have allowed millions of ordinary people to control application programs like spreadsheets and word processors. Graphics technology also supports windows (display boxes) environments on the workstation or personal computer screen, which allow users to work with different applications simultaneously, one in each window. Graphics also provide realistic interfacing to video games, flight simulators, and other simulations of reality or fantasy. The term *virtual reality* has been coined to refer to interaction with a computer-simulated world.

A challenge for computer science has been to develop algorithms for manipulating the myriad lines, triangles, and polygons that make up a computer image. In order for realistic on-screen images to be generated, the problems introduced in approximating objects as a set of planar units must be addressed. Edges of objects are smoothed so that the underlying construction from polygons is not visible, and representations of surfaces are textured. In many applications, still pictures are inadequate, and rapid display of real-time images is required. Both extremely efficient algorithms and state-of-the-art hardware are needed to accomplish such real-time animation.

Theory

COMPUTATIONAL METHODS AND NUMERICAL ANALYSIS

The mathematical methods needed for computations in engineering and the sciences must be transformed from the continuous to the discrete in order to be carried out on a computer. For example, the computer integration of a function over an interval is accomplished not by applying integral calculus to the function expressed as a formula but rather by approximating the area under the function graph with a sum of geometric areas obtained from evaluating the function at discrete points. Similarly, the solution of a differential equation is obtained as a sequence of discrete points determined, in simplistic terms, by approximating the true solution curve by a sequence of tangential line segments. When broken into discrete pieces in this way, many problems can be recast in the form of an equation involving a matrix (a rectangular array of numbers) that is solvable with techniques from linear algebra. Numerical analysis is the study of such computational methods. Several factors must be considered when applying numerical methods: (1) the conditions under which the method yields a solution, (2) the accuracy of the solution, and, since many methods are iterative, (3) whether the iteration is stable (in the sense of not exhibiting eventual error growth), and (4) how long (in terms of the number of steps) it will generally take to obtain a solution of the desired accuracy.

The need to study ever-larger systems of equations, combined with the development of supercomputers that allow many operations to proceed in parallel by assigning them to separate processing elements, has sparked much interest in the design and analysis of parallel computational methods. (See NUMERICAL ANALYSIS.)

DATA STRUCTURES AND ALGORITHMS

A major area of study in computer science has been the storage of data for efficient search and retrieval. The main memory of a computer is linear, consisting of a sequence of memory cells that are numbered 0, 1, 2, . . . in order. Similarly, the simplest data structure is the one-dimensional, or linear, array, in which array elements are numbered with consecutive integers and array contents may be accessed by the element numbers. Data items (a list of names, for example) are often stored in arrays, and efficient methods are sought to handle the array data. Search techniques must address, for example, how a particular name is to be found. One possibility is to examine the contents of each element in turn. If the list is long, it is important to sort the data first—in the case of names, to alphabetize them. Just as the alphabetizing of names in a telephone book greatly facilitates their retrieval by a user, the sorting of list elements significantly reduces the search time required by a computer algorithm as compared to a search on an unsorted list. Many algorithms have been developed for sorting data efficiently. These algorithms have application not only to data structures residing in main memory but, even more important, to the files that constitute information systems and databases.

Linear array

Although data items are stored consecutively in memory, they may be linked together by pointers (essentially, memory addresses stored with an item to indicate where the "next" item or items in the structure are found) so that the items appear to be stored differently than they actually are. An example of such a structure is the linked list, in which noncontiguously stored items may be accessed in a prespecified order by following the pointers from one item in the list to the next. The list may be circular, with the last item pointing to the first, or may have pointers in both directions to form a doubly linked list. Algorithms have been developed for efficiently manipulating such lists—searching for, inserting, and removing items.

Pointers provide the ability to link data in other ways. Graphs, for example, consist of a set of nodes (items) and linkages between them (known as edges). Such a graph might represent a set of cities and the highways joining them or the layout of circuit elements and connecting wires on a VLSI chip. Typical graph algorithms include solutions to traversal problems, such as how to follow the links from node to node (perhaps searching for a node with a particular property) in such a way that each node is visited only once. A related problem is the determination of the shortest path between two given nodes. A problem of practical interest in designing any network is to determine how many "broken" links can be tolerated before communications begin to fail. Similarly, in VLSI chip design it is important to know whether the graph representing a circuit is planar—that is, whether it can be drawn in two dimensions without any links crossing each other.

Computers

A computer might be described with deceptive simplicity as "an apparatus that performs routine calculations automatically." Such a definition would owe its deceptiveness to a naive and narrow view of calculation as a strictly mathematical process. In fact, calculation underlies many activities that are not normally thought of as mathematical. Walking across a room, for instance, requires many complex, albeit subconscious, calculations. Computers, too, have proved capable of solving a vast array of problems, from balancing a checkbook to even—in the form of guidance systems for robots—walking across a room.

Before the true power of computing could be realized, therefore, the naive view of calculation had to be overcome. The inventors who laboured to bring the computer into the world had to learn that the thing they were inventing was not just a number cruncher, not merely a calculator. For example, they had to learn that it was not necessary to invent a new computer for every new calculation and that a computer could be designed to solve numerous problems, even problems not yet imagined when the computer was built. They also had to learn how to tell such a general problem-solving computer what problem to solve. In other words, they had to invent programming.

They had to solve all the heady problems of developing such a device, of implementing the design, of actually building the thing. The history of the solving of these problems is the history of the computer. That history is covered in this article.

For coverage of the design and operation of computers, see COMPUTER SCIENCE. For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 735 and 10/23, and the *Index.*

The article is divided into the following sections:

Early history

COMPUTER PRECURSORS

The abacus. The earliest known calculating device is probably the abacus, which dates back at least to 1100 BC. It typically consisted of a rectangular frame with thin parallel rods strung with beads. Long before any systematic positional notation was adopted for the writing of numbers, the abacus assigned different units, or weights, to each rod. This scheme allowed a wide range of numbers to be represented by just a few beads and, together with the invention of zero in India, may have inspired the invention of the Hindu-Arabic number system. In any case, abacus beads can be readily manipulated to perform the common arithmetical operations—addition, subtraction, multiplication, and division—that are useful for commercial transactions and in bookkeeping.

The abacus is a digital device; that is, it represents values discretely. A bead is either in one predefined position or another, representing unambiguously, say, one or zero.

From Napier's logarithms to the first slide rule. Calculating devices took a different turn when John Napier, a Scottish mathematician, published his discovery of logarithms in 1614. Adding two 10-digit numbers is much simpler than multiplying them together, and the transformation of a multiplication problem into an addition problem is exactly what logarithms enable. This simplification is possible because of the following logarithmic property: the logarithm of the product of two numbers is equal to the sum of the logarithms of the numbers. By 1624, tables with 14 significant digits were available for the logarithms of numbers from 1 to 20,000, and scientists quickly adopted the new labour-saving tool for tedious astronomical calculations.

Most significant for the development of computing, the transformation of multiplication into addition greatly simplified the possibility of mechanization. Analog calculating devices based on Napier's logarithms—representing digital values with analogous physical lengths—soon appeared. In 1620 Edmund Gunter, an English mathematician who coined the terms *cosine* and *cotangent,* built a device for performing navigational calculations: the Gunter Scale or, as navigators simply called it, the gunter. Around 1632 an English clergyman and mathematician named William

Oughtred built the first slide rule, drawing on Napier's ideas. That first slide rule was circular, but Oughtred also built the first rectangular one in 1633.

The analog devices of Gunter and Oughtred had various advantages and disadvantages compared with digital devices. What is important is that the consequences of these design decisions were being tested in the real world.

From the Calculating Clock to the Arithmometer. In 1623 the German astronomer and mathematician Wilhelm Schickard built the first calculator. He described it in a letter to his friend the astronomer Johannes Kepler, and in 1624 he wrote again to explain that a machine that he had commissioned to be built for Kepler was, apparently along with the prototype, destroyed in a fire. He called it a Calculating Clock, and modern engineers have been able to reproduce it from details in his letters.

The first calculator or adding machine to be produced in any quantity and actually used was the Pascaline, or Arithmetic Machine, designed and built by the French mathematician-philosopher Blaise Pascal in 1642. It could do only addition and subtraction, with numbers being entered by manipulating its dials. Pascal invented the machine for his father, a tax collector, so it was the first business machine, too (if one does not count the abacus). He built 50 of them over the next 10 years.

Step Reckoner

In 1671 the German mathematician-philosopher Gottfried Wilhelm von Leibniz designed a calculating machine, the Step Reckoner, that expanded on Pascal's ideas and did multiplication by repeated addition and shifting. Leibniz was a strong advocate of the binary system. Binary numbers are ideal for machines because they require only two digits, which can easily be represented by the on and off states of a switch. When computers became electronic, the binary system was particularly appropriate because an electrical circuit is either on or off. This meant that on could represent true, off could represent false, and the flow of current would directly represent the flow of logic. Leibniz was prescient in seeing the appropriateness of the binary system in calculating machines. Nevertheless, the Step Reckoner represented numbers in decimal form, as positions on 10-position dials.

These devices were curiosities, but with the Industrial Revolution of the 18th century came a widespread need to perform repetitive operations efficiently. With other activities being mechanized, why not calculation? In 1820 Charles Xavier Thomas de Colmar of France effectively met this challenge when he built his Arithmometer, the first commercial mass-produced calculating device. It could perform addition, subtraction, multiplication, and, with some more elaborate user involvement, division. Based on Leibniz's technology, it was extremely popular and sold for 90 years. In contrast to the modern calculator's credit-card size, the Arithmometer was large enough to cover a desktop.

The Jacquard loom. Calculators remained a fascination after 1820, and their potential for commercial use was well understood. Many other mechanical devices built during the 19th century also performed repetitive functions more or less automatically, but few had any application to computing. There was one major exception: the Jacquard loom, invented in 1804–05 by a French weaver, Joseph-Marie Jacquard.

The Jacquard loom wove textiles; it could also be called the first practical information-processing device. The loom worked by tugging various-coloured threads into patterns by means of an array of rods. By inserting a card punched with holes, an operator could control the motion of the rods and thereby alter the pattern of the weave. Moreover, the loom was equipped with a card-reading device that slipped a new card from a prepunched deck into place every time the shuttle was thrown so that complex weaving patterns could be automated.

What was extraordinary about the device was that it transferred the design process from a labour-intensive weaving stage to a card-punching stage. Once the cards had been punched and assembled, the design was complete, and the loom implemented the design automatically. The Jacquard loom, therefore, could be said to be programmed for different patterns by these decks of punched cards.

For those intent on mechanizing calculations, the Jacquard loom provided important lessons: the sequence of operations that a machine performs could be controlled to make the machine do something quite different; a punched card could be used as a medium for directing the machine; and, most important, it was possible to direct a device to perform different tasks by feeding it instructions in a sort of language—*i.e.*, the machine could be made programmable. It is not too great a stretch to say that, in the Jacquard loom, programming was invented before the computer. The close relationship between the device and the program became apparent some 20 years later, with Charles Babbage's invention of the first computer.

Invention of programming

The Arithmetic Machine, or Pascaline, a French monetary (non-decimal) calculator designed by Blaise Pascal *c.* 1642. Numbers could be added by turning the wheels (located along the bottom of the machine) clockwise and subtracted by turning the wheels counterclockwise. Each digit in the answer was displayed in a separate window, visible at the top of the photograph.

THE FIRST COMPUTER

By the second decade of the 19th century, a number of ideas necessary for the invention of the computer were in the air. First, the potential benefits to science and industry of being able to automate routine calculations was appreciated, as it had not been a century earlier. Specific methods to make automated calculation more practical, such as doing multiplication by adding logarithms or by repeating addition, had been invented, and experience with both analog and digital devices had shown some of the benefits of each approach. Finally, the Jacquard loom had shown the benefits of directing a multipurpose device through coded instructions, and it had demonstrated how punched cards could be used to modify those instructions quickly and flexibly. It was a mathematical genius in England who began to put all of these pieces together.

The Difference Engine. As a founding member of the Royal Astronomical Society, Charles Babbage had seen a clear need to design and build a mechanical device that could automate long, tedious astronomical calculations. He began by writing a letter in 1822 to Sir Humphry Davy, president of the Royal Society, about the possibility of automating the construction of mathematical tables—specifically, logarithm tables for use in navigation. Tables then in use often contained errors, which could be a life-and-death matter for sailors at sea, and Babbage argued that by automating the production of the tables he could assure their accuracy. Having gained support in the society for his Difference Engine, as he called it, Babbage next turned to the British government to fund development, obtaining one of the first government grants for research and technological development anywhere in the world.

Babbage approached the project very seriously: he hired a master machinist, set up a fireproof workshop, and built a dust-proof environment for testing the device. Up until then calculations were rarely carried out to more than 6 digits; Babbage planned routinely to produce 20- or 30-digit results.

The Difference Engine was a digital device: it operated on discrete digits rather than smooth quantities, and the digits were decimal (0–9), represented by positions on toothed wheels. When one of the toothed wheels turned from 9 to 0, it caused the next wheel to advance one position, carry-

ing the digit just as Leibniz's Step Reckoner calculator had operated. The Difference Engine was more than a simple calculator, however; it mechanized not just a single calculation but a whole series of calculations on a number of variables to solve a complex problem. It went far beyond calculators in other ways as well. Like modern computers, the Difference Engine had storage—that is, a place where data could be held temporarily for later processing—and it was designed to stamp its output into soft metal, which could later be used to produce a printing plate.

Nevertheless, the Difference Engine performed only one operation. After all of its data registers had been loaded with the original data, the single operation would be repeatedly applied to all of the registers, ultimately producing a solution. Still, in complexity and audacity of design it dwarfed any calculating device then in existence.

The full engine, designed to be room-sized, was never built, at least not by Babbage. Although he sporadically received several government grants—governments changed, funding often ran out, and he had to personally bear some of the financial costs—he was working at or near the tolerances of the construction methods of the day, and he ran into numerous construction difficulties. All design and construction ceased in 1833, when Joseph Clement, the machinist responsible for actually building the machine, refused to continue unless he was prepaid.

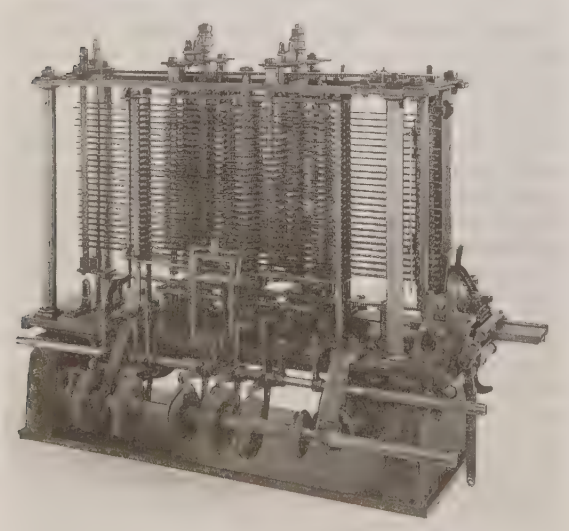
The Analytical Engine. While working on the Difference Engine, Babbage began to imagine ways to improve it. Chiefly he thought about generalizing its operation so that it could perform other kinds of calculations. By the time the funding had run out in 1833, he had conceived of something far more revolutionary: a general-purpose computing machine called the Analytical Engine.

The first computer

The Analytical Engine was to be a general-purpose, fully program-controlled, automatic mechanical digital computer. It would be able to perform any calculation set before it. Before Babbage there is no evidence that anyone had ever conceived of such a device, let alone attempted to build one. The machine was designed to consist of four components: the mill, the store, the reader, and the printer. These components are the essential components of every computer today. The mill was the calculating unit, analogous to the central processing unit (CPU) in a modern computer; the store was where data were held prior to processing, exactly analogous to memory and storage in today's computers; and the reader and printer were the input and output devices.

As with the Difference Engine, the project was far more complex than anything theretofore built. The store was to be large enough to hold 1,000 50-digit numbers; this was larger than the storage capacity of any computer built before 1960. The machine was to be steam-driven and run by one attendant. The printing capability was also ambitious, as it had been for the Difference Engine: Babbage wanted to automate the process as much as possible, right up to producing printed tables of numbers.

Science Museum/Science & Society Picture Library



A portion of Charles Babbage's Analytical Engine, completed in 1910. Only partially built at the time of Babbage's death in 1871, this portion contains the "mill" (functionally analogous to a modern computer's central processing unit) and a printing mechanism.

The reader was another new feature of the Analytical Engine. Data (numbers) were to be entered on punched cards, using the card-reading technology of the Jacquard loom. Instructions were also to be entered on cards, another idea taken directly from Jacquard. The use of instruction cards would make it a programmable device and far more flexible than any machine then in existence. Another element of programmability was to be its ability to execute instructions in other than sequential order. It was to have a kind of decision-making ability in its conditional control transfer, also known as conditional branching, whereby it would be able to jump to a different instruction depending on the value of some data.

By most definitions, the Analytical Engine was a real computer—or would have been, had not Babbage run into implementation problems again. Actually building his ambitious design was judged infeasible, given the current technology, and Babbage's failure to generate the promised mathematical tables with his Difference Engine had dampened enthusiasm for further government funding. Indeed, it was apparent to the British government that Babbage was more interested in innovation than in constructing tables. All the same, Babbage's Analytical Engine was something completely new. Its most revolutionary feature was the ability to change its operation by changing the instructions on punched cards. Until this breakthrough, all of the mechanical aids to calculation were merely calculators.

EARLY BUSINESS MACHINES

Throughout the 19th century, business machines were becoming more common. Calculators became available as a tool of commerce in 1820, and in 1874 the Remington Arms Company, Inc., sold the first commercially viable typewriter. Other machines were invented for other specific business tasks. None of these machines was a computer, but they did advance the state of practical mechanical knowledge—knowledge that would be used in computers later. One of these machines was invented in response to a sort of constitutional crisis in the United States: the census tabulator.

Herman Hollerith's census tabulator. The U.S. Constitution mandates that a census of the population be performed every 10 years. The first attempt at any mechanization of the census was in 1870, when statistical data were transcribed onto a rolling paper tape displayed through a small slotted window. As the U.S. population exploded in the 19th century and the number of census questions expanded, the urgency of further mechanization became increasingly clear.

Herman Hollerith first saw the pressing need for automating the tabulation of statistical data from the 1880 census while employed by the Census Office. Over the next 10 years Hollerith refined his ideas, obtaining his first patent in 1884 for a machine to punch and count cards. He then organized the health records for Baltimore, Maryland, for New York City, and for the state of New Jersey—all in preparation for winning the contract to tabulate the 1890 U.S. Census. The success of the U.S. census opened European governments to Hollerith's machines. Most notably, a contract with the Russian government may have induced him to incorporate as the Tabulating Machine Company in 1896.

Other early business machine companies. Improvements in calculators continued: by the 1880s, they could add in the accumulation of partial results and store past results as well as print. Then, in 1892, William Seward Burroughs, who along with two other St. Louis, Missouri, businessmen had started the American Arithmometer Company in 1886 in order to build adding machines, obtained a patent for one of the first truly practical, and commercially successful, calculators. Burroughs died in 1898, and his company was reorganized as the Burroughs Adding Machine Company in Detroit, Michigan, in 1905.

All the calculators sold at this time were designed for

commercial purposes, not scientific research. By the turn of the century, commercial calculating devices were in common use. As a result, many of the business machine companies in the United States were doing well, including Hollerith's Tabulating Machine Company.

Origin of IBM

In 1911 several of these companies combined to form the Computing-Tabulating-Recording Company, or CTR. In 1914 Thomas Watson became president of CTR, and 10 years later CTR changed its name to International Business Machines Corporation (IBM). In the second half of the 20th century IBM would become the giant of the world computer industry, but such commercial gains did not take place until enormous progress had been made in the theoretical understanding of the modern computer during the remarkable decades of the 1930s and '40s.

Invention of the modern computer

EARLY EXPERIMENTS

As the technology for realizing a computer was being honed by the business machine companies in the early 20th century, the theoretical foundations were being laid in academia. During the 1930s, two important strains of computer-related research were being pursued at two universities in Cambridge, Massachusetts. One strain produced the Differential Analyzer, the other a series of devices ending with the Harvard Mark IV.

Vannevar Bush's Differential Analyzer. In 1930 Vannevar Bush at the Massachusetts Institute of Technology (MIT) developed the first modern analog computer. The Differential Analyzer, as he called it, could be used to solve certain classes of differential equations, a type of problem common in physics and engineering applications that is often very tedious to solve. Variables were represented by shaft motion, and addition and multiplication were accomplished by feeding the values into a set of gears. Integration was carried out by means of a knife-edged wheel rotating at a variable radius on a circular table. The individual mechanical integrators were then interconnected to solve a set of differential equations.

The Differential Analyzer proved highly useful, and a number of them were built and used at various universities. Still, the device was limited to solving this one class of problem, and, as is the case for all analog devices, it produced approximate, albeit practical, solutions. Nevertheless, important applications for analog computers still exist, particularly for simulating complicated dynamical systems such as aircraft flight, nuclear power plant operations, and chemical reactions.

Howard Aiken's digital calculators. While Bush was working on analog computing at MIT, across town Harvard professor Howard Aiken was working with digital devices for calculation. He had begun to realize in hardware something like Babbage's Analytical Engine. Starting in 1937, he laid out detailed plans for a series of four calculating machines of increasing sophistication, based on different technologies, from the largely mechanical Mark I to the electronic Mark IV.

IBM Archives

The Harvard Mark I, an electromechanical computer designed by Howard Aiken, was more than 50 feet (15 metres) long and contained some 750,000 components; it was used to make ballistics calculations during World War II.

Aiken was methodically exploring the technological advances made since the mechanical assembly and steam power available to Babbage. Electromagnetic relay circuits were already being used in business machines, and the vacuum tube—a switch with no moving parts, very high speed action, and greater reliability than electromechanical relays—was quickly put to use in the early experimental machines. The business machines of the time used plugboards (something like telephone switchboards) to route data manually, and Aiken chose not to use them for the specification of instructions. This turned out to make his machine much easier to program than the more famous ENIAC, designed somewhat later, which had to be manually rewired for each program.

From 1939 to 1944 Aiken, in collaboration with IBM, developed his first fully functional computer, known as the Harvard Mark I. The machine, like Babbage's, was huge: more than 50 feet (15 metres) long, weighing five tons, and consisting of about 750,000 separate parts, it was mostly mechanical. For input and output it used three paper tape readers, two card readers, a card punch, and two typewriters. Aiken developed three more such machines (Mark II–IV) over the next few years and is credited with developing the first fully automatic large-scale calculator.

THE TURING MACHINE

The formalist program

Alan Turing, while a student at University of Cambridge in the 1930s, was inspired by German mathematician David Hilbert's formalist program, which sought to demonstrate that any mathematical problem can potentially be solved by an algorithm—that is, by a purely mechanical process. Turing interpreted this to mean a computing machine and, in order to design such a machine (known to posterity as the "Turing machine"), he needed to develop an unambiguous definition of the essence of a computer. In doing so, Turing worked out in great detail the basic concepts of a universal computing machine (1936)—that is, a computing machine that could, at least in theory, do anything that a special-purpose computing device could do. In particular, it would not be limited to doing arithmetic. The internal states of the machine could represent numbers, but they could equally well represent logic values or letters. In fact, Turing believed that everything could be represented symbolically, even abstract mental states, and he was one of the first advocates of the artificial-intelligence position that computers can potentially "think."

Turing's work up to this point was entirely abstract, entirely a theoretical demonstration. But he made it clear from the start that his results implied the possibility of building a machine of the sort he described. His work characterized the abstract essence of any computing device so well that it was in effect a challenge to actually build one.

PIONEERING WORK

The Atanasoff-Berry Computer. The first special-purpose electronic computer was built by John Vincent Atanasoff, a physicist and mathematician at Iowa State College (now Iowa State University), during 1937–42. Together with his graduate assistant Clifford E. Berry, Atanasoff built a successful small prototype in 1939 for the purpose of testing two ideas central to his design: capacitors to store data in binary form and electronic logic circuits to perform addition and subtraction. They then began the design and construction of a larger, more general-purpose computer, known as the Atanasoff-Berry Computer, or ABC.

Various components of the ABC were designed and built from 1939 to 1942, but development was discontinued with the onset of World War II. The ABC featured about 300 vacuum tubes for control and arithmetic calculations, use of binary numbers, logic operations, memory capacitors, and punched cards as input/output units.

The first computer network. Between 1940 and 1946 George Stibitz and his team at Bell Laboratories built a series of machines with telephone technologies—*i.e.*, employing electromechanical relays. These were the first machines to serve more than one user and the first to work remotely over telephone lines. Based on slow mechanical

relays rather than electronic switches, they became obsolete almost as soon as they were constructed.

DEVELOPMENTS DURING WORLD WAR II

England and Colossus. The exigencies of war gave impetus and funding to computer research. For example, in Britain the impetus was code-breaking. The Ultra project was funded with much secrecy to develop the technology necessary to crack ciphers and codes produced by German electromechanical devices. The first code-breaking machine, Colossus, also known as the Mark I, was built at Bletchley Park, a government research centre north of London, and was operational, cracking German codes, by December 1943. It employed approximately 1,800 vacuum tubes for computations. Successively larger and more elaborate versions were built over the next two years.

The Ultra project

The Ultra project had a gifted mathematician associated with the Bletchley Park effort, and one familiar with codes. Alan Turing, who had earlier articulated the concept of a universal computing device, may have taken the project farther in the direction of a general-purpose device than his government originally had in mind.

Germany and Z4. Meanwhile in Germany, engineer Konrad Zuse began building calculating machines in 1936, all of which used binary representation in order to simplify construction. This had the added advantage of making the connection with logic clearer, and Zuse worked out the details of how the operations of logic (*e.g.,* AND, OR, and NOT) could be mapped onto the design of the computer's circuits. Zuse also spent more time than his predecessors and contemporaries developing software for his computer, the language in which it was to be programmed. Although all of his early prewar machines were really calculators—not computers—his Z3, completed in December 1941, was the first program-controlled processor.

Zuse began construction of the Z4 in 1943 with funding from the Air Ministry. Like his Z3, the Z4 used electromechanical relays, in part because of the difficulty of acquiring the roughly 2,000 necessary vacuum tubes in wartime Germany.

Floating-point numbers

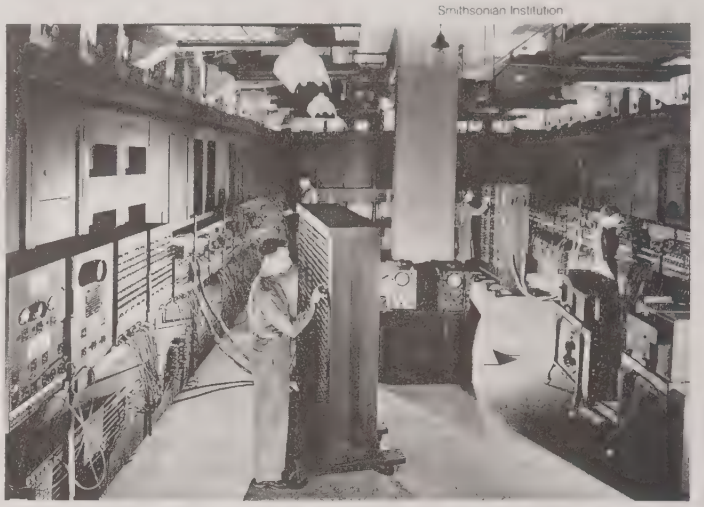
Zuse's use of floating-point representation for numbers—the significant digits, known as the mantissa, are stored separately from a pointer to the decimal point, known as the exponent, allowing a very large range of numbers to be handled—was far ahead of its time. The Z4's program was punched on used movie film and was separate from the mechanical memory for data (in other words, there was no stored program). The machine was relatively reliable, but it had no decision-making ability.

The United States and ENIAC. In the United States, government funding went to a project led by John Mauchly, J. Presper Eckert, Jr., and their colleagues at the Moore School of Electrical Engineering at the University of Pennsylvania; their objective was an all-electronic computer. Under contract to the army, and under the direction of Herman Goldstine, work began in early 1943 on the Electronic Numerical Integrator and Computer (ENIAC). The next year, mathematician John von Neumann, already on full-time leave from the Institute for Advanced Studies (IAS), Princeton, New Jersey, for various government research projects (including the Manhattan Project), began frequent consultations with the group.

ENIAC was something less than the dream of a universal computer. Designed for the specific purpose of computing values for artillery range tables, it lacked some features that would have made it a more generally useful machine. Unlike Aiken's machine, it used plugboards for communicating instructions to the machine; this had the advantage that, once the instructions were thus "programmed," the machine ran at electronic speed. Instructions read from a card reader or other slow mechanical device would not have been able to keep up with the all-electronic ENIAC. The disadvantage was that it took days to rewire the machine for each new problem. This was such a liability that only with some generosity could it be called programmable.

Nevertheless, ENIAC was the most powerful calculating device built to date. It was the first programmable general-purpose electronic digital computer. Like Babbage's Analytical Engine and the Colossus, but unlike Aiken's Mark I, Zuse's Z4, and Stibitz's telephone-savvy machine, it did have conditional branching—that is, it had the ability to execute different instructions or to alter the order of execution of instructions, based on the value of some data. This gave ENIAC a lot of flexibility and meant that, while it was built for a specific purpose, it could be used for a wider range of problems.

Smithsonian Institution



The ENIAC computer, installed at the Moore School of Electrical Engineering, University of Pennsylvania, 1945. Containing more than 100,000 components and weighing approximately 30 tons, it was the first programmable general-purpose electronic digital computer.

ENIAC was enormous. It occupied the 50-by-30-foot basement of the Moore School, where its 40 panels were arranged, U-shaped, along three walls. Each of the units was about 2 feet wide by 2 feet deep by 8 feet high. With approximately 18,000 vacuum tubes, 70,000 resistors, 10,000 capacitors, 6,000 switches, and 1,500 relays, it was easily the most complex electronic system theretofore built. ENIAC ran continuously (in part to extend tube life), generating 150 kilowatts of heat, and could execute up to 5,000 additions per second, several orders of magnitude faster than its electromechanical predecessors. It and subsequent computers employing vacuum tubes are known as first-generation computers. (With 1,500 mechanical relays, ENIAC was still transitional to later, fully electronic computers.)

First-generation computers

Completed by 1946, ENIAC had cost the government $400,000, and the war it was designed to help win was over. Its first task was doing calculations for the construction of a hydrogen bomb. A portion of the machine is on exhibit at the Smithsonian Institution in Washington, D.C.

TOWARD THE CLASSICAL COMPUTER

Bigger brains. The computers built during the war were built under unusual constraints. The British work was largely focused on code breaking, the American work on computing projectile trajectories and calculations for the atomic bomb. The computers were built as special-purpose devices, although they often embodied more general-purpose computing capabilities than their specifications called for. The vacuum tubes in these machines were not entirely reliable, but with no moving parts they were more reliable than the electromechanical switches they replaced, and they were much faster. Reliability was an issue, since Colossus used some 1,500 tubes and ENIAC on the order of 18,000. But ENIAC was, by virtue of its electronic realization, 1,000 times faster than the Harvard Mark I. Such speed meant that the machine could perform calculations that were theretofore beyond human ability. Although tubes were a great advance over the electromechanical realization of Aiken or the steam-and-mechanical model of Babbage, the basic architecture of the machines (that is, the functions they were able to perform) was not much advanced beyond Babbage's designs.

After the war, efforts focused on fulfilling the idea of a general-purpose computing device. In 1945, before ENIAC

was even finished, planning began at the Moore School for ENIAC's successor, the Electronic Discrete Variable Automatic Computer, or EDVAC. ENIAC was hampered, as all previous electronic computers had been, by the need to use one vacuum tube to store each bit, or binary digit. The feasible number of vacuum tubes in a computer also posed a practical limit on storage capacity—beyond a certain point, vacuum tubes are bound to burn out as fast as they can be changed. For EDVAC, Eckert had a new idea for storage.

The mercury delay line

In 1880 the French physicists Pierre and Jacques Curie had discovered that applying an electric current to a quartz crystal would produce a characteristic vibration and vice versa. During the 1930s at Bell Laboratories, William Shockley, later coinventor of the transistor, had demonstrated a device—a tube, called a delay line, containing water and ethylene glycol—for effecting a predictable delay in information transmission. Eckert had already built and experimented in 1943 with such a delay line (using mercury) in conjunction with radar research, and sometime in 1944 he hit upon the new idea of placing a quartz crystal at each end of the mercury delay line in order to sustain and modify the resulting pattern. In effect, he had invented a new storage device. Whereas ENIAC had required one tube per bit, EDVAC could use a delay line and 10 vacuum tubes to store 1,000 bits. Before the invention of the magnetic core memory and the transistor, which would eliminate the need for vacuum tubes altogether, the mercury delay line was instrumental in increasing computer storage and reliability.

Von Neumann machines. The design of the modern, or classical, computer did not fully crystallize until the publication of a 1946 paper by Arthur Burks, Herman Goldstine, and John von Neumann. Although many researchers contributed ideas directly or indirectly to the paper, von Neumann was the principal author, and it is frequently cited as the birth certificate of computer science.

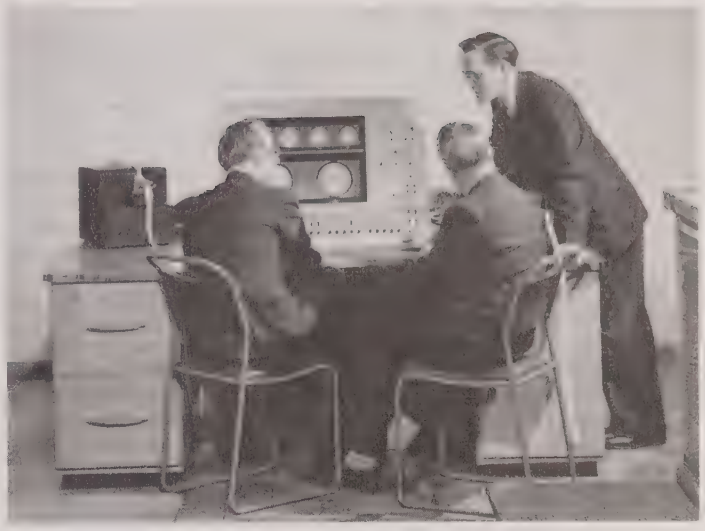
Among the principles enunciated in the paper were that data and instructions should be kept in a single store and that instructions should be encoded so as to be modifiable by other instructions. This was an extremely critical decision, because it meant that one program could be treated as data by another program; its inclusion by von Neumann's group made possible high-level programming languages and most of the advances in software of the following 50 years. Subsequently, computers with stored programs became known as von Neumann machines.

One problem that the stored-program idea solved was the need for rapid access to instructions. ENIAC had used plugboards, which had the advantage of enabling the instructions to be read in electronically, rather than by much slower mechanical card readers, but it also had the disadvantage of making ENIAC very hard to program. But if the instructions could be stored in the same electronic memory that held the data, they could be accessed as quickly as needed. One immediately obvious consequence was that EDVAC would need a lot more memory than ENIAC.

The first commercial computer

The first stored-program machines. Engineers in Britain beat the Americans to the goal of building the first stored-program digital computer. At the University of Manchester, Frederic C. Williams and Tom Kilburn built a simple stored-program computer, known as the Baby, in 1948. This was built to test their invention of a way to store information on a cathode-ray tube that enabled direct access (in contrast to the mercury delay line's sequential access) to stored information. Although faster than Eckert's storage method, it proved somewhat unreliable. Nevertheless, it became the preferred storage method for most of the early computers worldwide that were not already committed to mercury delay lines.

By 1949 Williams and Kilburn had extended the Baby to a full-size computer, the Manchester Mark I. This had two major new features that were to become computer standards, a two-level store and instruction modification registers (which soon evolved into index registers). A magnetic drum was added to provide a random-access secondary storage device. Until machines were fitted with index registers, every instruction that referred to an address that varied as the program ran—*e.g.*, an array element—had to be preceded by instructions to alter its address to the current required value. Four months after the Baby first worked, the British government contracted the electronics firm of Ferranti to build a production computer based on the prospective Manchester Mark I. This became the Ferranti Mark I—the first commercial machine—of which nine were sold.



Tom Kilburn stands beside the console of the Ferranti Mark I computer, *c.* 1950.

At the University of Cambridge, meanwhile, Maurice Wilkes and others built what is recognized as the first full-size stored-program computer to provide a formal computing service for users. The Electronic Delay Storage Automatic Calculator (EDSAC) was built on von Neumann's principles and, like the Manchester Mark I, became operational in 1949. Wilkes built the machine chiefly to study programming issues, which he realized would become as important as the hardware details.

Whirlwind. New hardware continued to be invented, though. In the United States, Jay Forrester of MIT and Jan Aleksander Rajchman of the Radio Corporation of America came up with a new kind of memory based on magnetic cores that was fast enough to enable MIT to build the first real-time computer, Whirlwind. A real-time computer is one that can respond seemingly instantly to basic instructions, thus allowing an operator to interact with a "running" computer.

Real-time computing

UNIVAC

After leaving the Moore School, Eckert and Mauchly struggled to obtain capital to build their latest design, a computer they called the Universal Automatic Computer, or UNIVAC. The partners delivered the first UNIVAC to the U.S. Bureau of the Census in March 1951, although their company, their patents, and their talents had been acquired by Remington Rand, Inc., in 1950. Although it owed something to experience with ENIAC, UNIVAC was built from the start as a stored-program computer, so it was really different architecturally. It used an operator keyboard and console typewriter for input and magnetic tape for all other input and output. Printed output was recorded on tape and then printed by a separate tape printer.

The UNIVAC I was designed as a commercial data-processing computer, intended to replace the punched-card accounting machines of the day. It could read 7,200 decimal digits per second (it did not use binary numbers), making it by far the fastest business machine yet built. Its use of Eckert's mercury delay lines greatly reduced the number of vacuum tubes needed (to 5,000), thus enabling the main processor to occupy a "mere" 14.5 feet by 7.5 feet by 9 feet. It was a true business machine, signaling the convergence of academic computational research with the office automation trend of the late 19th and early 20th centuries. As such, it ushered in the era of "Big Iron," or large, mass-produced computing equipment.

The age of Big Iron

A snapshot of computer development in the early 1950s would show a number of companies and laboratories in competition—technological competition and increasingly earnest business competition—to produce the few computers then demanded for scientific research. Several computer-building projects had been launched immediately after the end of World War II, primarily in the United States and Britain. These projects were inspired chiefly by a 1946 document produced by a group working under the direction of mathematician John von Neumann of the Institute for Advanced Study at Princeton University. The IAS paper, as von Neumann's document became known, articulated the concept of the stored program—perhaps the single largest innovation in the history of the computer. Most computers built in the years following the paper's distribution were designed according to its plan, yet by 1950 there were still only a handful of working stored-program computers.

Business use at this time was marginal because the machines were so hard to use. Although computer makers such as Remington Rand, Burroughs, and IBM had begun building machines to the IAS specifications, it was not until 1954 that a real market for business computers began to emerge. The IBM 650, delivered at the end of 1954 for colleges and businesses, was a decimal implementation of the IAS design. With this low-cost magnetic drum computer, which sold for about $200,000 apiece (compared with about $1,000,000 for the scientific model, the IBM 701), IBM had a hit, eventually selling about 1,800 of them. In addition, by offering universities that taught computer science courses around the IBM 650 an academic discount program, IBM established a cadre of engineers and programmers for their machines.

IBM Archives

An IBM 650 computer system, *c.* 1954. Relatively inexpensive, compact, and easy to operate, the IBM 650 quickly became the most widely used computer for business applications.

A snapshot of the era would also show what could be called the sociology of computing. The actual use of computers was restricted to a small group of trained experts, and there was resistance to the idea that this group should be expanded by making the machines easier to use. Machine time was expensive, more expensive than the time of the mathematicians and scientists who needed to use the machines, and computers could process only one problem at a time. As a result, the machines were in a sense held in higher regard than the scientists. If a task could be done by a person, it was thought that the machine's time should not be wasted with it. The public's perception of computers was not positive either. If motion pictures of the time can be used as a guide, the popular image was of a room-filling brain attended by white-coated technicians, mysterious and somewhat frightening—about to eliminate jobs through automation.

Yet the machines of the early 1950s were not much more capable than Babbage's designs of the 1830s. Although in principle these were general-purpose computers, they were still largely restricted to doing math problems. They often lacked the means to perform logical operations, and they had little text-handling capability—for example, lowercase letters were not even representable in the machines, even if there had been devices capable of printing them.

These machines could be operated only by experts, and preparing a problem for computation took a long time. With only one person at a time able to use a machine, major bottlenecks were created.

In sum, the machines were expensive and the market was still small. To be useful in a broader business market, or even in a broader scientific market, computers would need application programs: word processors, database programs, and so on. These applications in turn would require programming languages in which to write them and operating systems to manage them.

PROGRAMMING LANGUAGES

Early computer language development. *Machine language.* One implication of the stored-program model was that programs could read and operate on other programs as data; that is, they would be capable of self-modification. One of the very first employments of self-modification was for computer language translation, "language" here referring to the instructions that make the machine work. Although the earliest machines worked by flipping switches, the stored-program machines were driven by stored coded instructions, and the conventions for encoding these instructions were referred to as the machine's language.

Machine language

The vocabulary and rules of syntax of machine language tend to be highly detailed and very far from the natural or mathematical language in which problems are normally formulated. The desirability of automating the translation of problems into machine language was immediately evident to users, who either had to become computer experts and programmers themselves in order to use the machines or had to rely on experts and programmers who might not fully understand the problems they were translating. Automatic translation from pure mathematics, or some other "high-level language," to machine language was therefore necessary before computers would be useful to a broader class of users.

The IAS model guaranteed that the stored-program computer would have the power to serve as its own coding machine. The translator program, written in machine language and running on the computer, would be fed the target program as data, and it would output machine-language instructions. This plan was altogether feasible, but the cost of the machines was so great that it was not seen as cost-effective to use them for anything that a human could do—including program translation.

Two forces, in fact, argued against the early development of high-level computer languages. One was skepticism that anyone outside the "priesthood" of computer operators could or would use computers directly. Consequently, early computer-makers saw no need to make them more accessible to people who would not use them anyway. A second reason was efficiency. Any translation process would necessarily add to the computing time necessary to solve a problem, and mathematicians and operators were far cheaper by the hour than computers.

Interpreters. High-level languages (HLL) for writing computer code were attempted right from the start of the stored-program era in the late 1940s. Shortcode was the first such language. Suggested by John Mauchly in 1949, it was implemented by William Schmitt for the BINAC computer in that year and for UNIVAC in 1950. Shortcode went through multiple steps: first it converted the alphabetic statements of the language to numeric codes, and then it translated these numeric codes into machine language. It was an interpreter, meaning that it translated HLL statements and executed, or performed, them one at a time—a slow process. Because of their slow execution, interpreters are now rarely used outside of program development, where they may help a programmer to locate errors quickly.

Shortcode

Compilers. An alternative to this approach is what is now known as compilation. In compilation, the entire HLL program is converted to machine language and stored for later execution. Although translation may take many hours, or even days, once the translated program is stored it can be recalled anytime in the form of a fast-executing machine-language program.

In 1952 Heinz Rutishauser wrote an influential paper in which he laid down the foundations of compiler construction and described two proposed compilers. Rutishauser was later involved in creating one of the most carefully defined programming languages of this early era, ALGOL.

Then, in September 1952, Alick Glennie, a student at the University of Manchester, England, created the first of several programs called Autocode for the Manchester Mark I. Autocode was the first compiler. Glennie's compiler had little influence, however. When J. Halcombe Laning created a compiler for the Whirlwind computer at MIT two years later, he met with similar lack of interest. Both compilers had the fatal drawback of producing code that ran slower (10 times slower, in the case of Laning's) than code handwritten in machine language.

Autocode

FORTRAN, COBOL, and ALGOL. *Grace Murray Hopper.* While the high cost of computer resources placed a premium on fast hand-coded machine-language programs, one individual worked tirelessly to promote high-level programming languages and their associated compilers. Grace Murray Hopper programmed the Mark I under the direction of Aiken. After World War II she joined Eckert and Mauchly at their new company and, among other things, wrote compiler software for BINAC and the UNIVAC systems. Throughout the 1950s Hopper campaigned earnestly for high-level languages across the United States. Such urging found a receptive audience at IBM, where the management wanted to add computers to the company's successful line of business machines.

Smithsonian Institution

IBM develops FORTRAN. In the early 1950s John Backus convinced his managers at IBM to let him put together a team to design a language and write a compiler for it. He had a machine in mind: the IBM 704, which had built-in floating-point math operations. That the 704 used floating-point representation made it especially useful for scientific work, and Backus believed that a scientifically oriented programming language would make the machine even more attractive. Still, he understood the resistance to anything that slowed a machine down, and he set out to produce a language and a compiler that would produce code that ran virtually as fast as hand-coded machine language—and at the same time made the program-writing process a lot easier. By 1954 Backus and a team of programmers had designed the language, which they called FORTRAN. Programs written in FORTRAN looked a lot more like mathematics than machine instructions. The compiler was written, and the language was released with a professional-looking typeset manual in 1957.

FORTRAN took another step toward making programming more accessible by allowing comments in the programs. The ability to insert annotations, marked to be ignored by the translator program but readable by a human, meant that a well-annotated program could be read in a certain sense by people with no programming knowledge at all. For the first time a nonprogrammer could get an idea what a program did—or at least what it was intended to do—by reading the code. It was an obvious but powerful step in opening up computers to a wider audience. FORTRAN has continued to evolve, and it retains a large user base in academia and among scientists.

Non-executable comments

COBOL. Around the time that Backus and his team invented FORTRAN, Hopper's group at UNIVAC were developing Flow-matic, which used a more English-like syntax and vocabulary. Flow-matic led to COBOL (Common Business-Oriented Language) in 1959. COBOL was explicitly a business programming language with a very verbose English-like style. It became central to the wide acceptance of computers by business after 1959.

ALGOL. During the late 1950s a multitude of programming languages appeared. This proliferation of incompatible specialized languages spurred an interest in North America and Europe to create a single "second-generation" language. A transatlantic committee soon formed to determine specifications for ALGOL, as the new language would be called. Backus, on the American side, and Heinz Rutishauser, on the European side, were among the most influential committee members.

Second-generation language

Although ALGOL introduced some important language ideas, it was not a commercial success. Customers preferred a known specialized language, such as FORTRAN or COBOL, to an unknown general-programming language. Only Pascal, a scientific programming-language offshoot of ALGOL, survives.

OPERATING SYSTEMS

Control programs. In order to make the early computers truly useful and efficient, two major innovations in software were needed. One was high-level programming languages. The other was control. Today the system-wide control functions of a computer are generally subsumed under the term *operating system,* or OS. An operating system handles the behind-the-scenes activities of a computer, such as orchestrating the transitions from one program to another and managing access to disk storage and peripheral devices.

The need for a supervisor program was quickly recognized, but the design requirements for such a program were daunting. The supervisor program would have to run in parallel with an application program somehow, monitor its actions in some way, and seize control when necessary. Moreover, the essential—and difficult—feature of even a rudimentary supervisor program was the interrupt facility. It had to be able to stop a running program when necessary but save the state of the program and all registers so that after the interruption was over the program could be restarted from where it left off. The first computer with a true interrupt system was the UNIVAC 1103A, which had a single interrupt triggered by one fixed condition.

Interrupt facility

However, it was IBM that created, and dominated, a market for business computers. IBM established its primacy primarily through one invention: the IBM 360 operating system.

The IBM 360. IBM had been selling business machines since early in the century and had built Aiken's computer to his architectural specifications. But the company had been slow to implement the stored-program digital computer architecture of the early 1950s. It did develop the IBM 650, a decimal implementation of the IAS plan—and the first computer to sell more than 1,000 units.

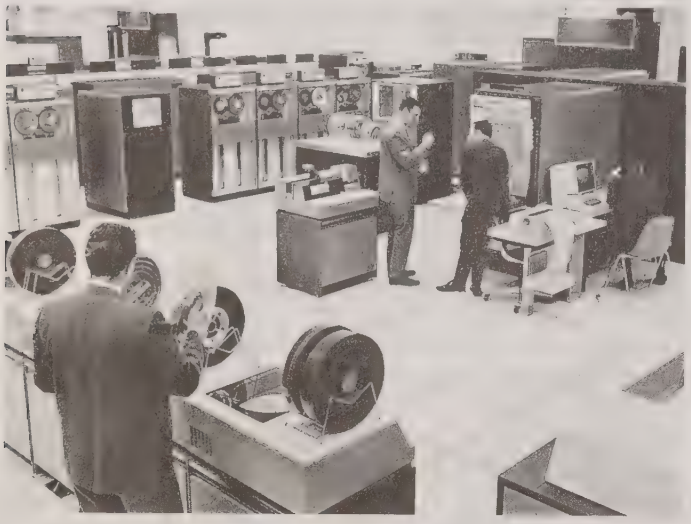
The invention of the transistor in 1947 led IBM, in the late 1950s, to reengineer its early machines from electromechanical or vacuum tube to transistor technology. These transistorized machines are commonly referred to as second-generation computers. Two IBM inventions, the magnetic disk and the high-speed chain printer, led to an

Second-generation computers

expansion of the market and to the unprecedented sale of 12,000 computers of one model: the IBM 1401. The chain printer required a lot of magnetic core memory, and IBM engineers packaged up the printer support, core memory, and disk support into the 1401, one of the first computers to use this solid-state technology.

IBM had several lines of computers developed by independent groups of engineers within the company: a scientific-technical line, a commercial data-processing line, an accounting line, a decimal machine line, and a line of supercomputers. Each line had a distinct hardware-dependent operating system, and each required separate development and maintenance of its associated application software. In the early 1960s IBM began designing a machine that would take the best of all these disparate lines, add some new technology and new ideas, and replace all of the company's computers with one single line, the 360. At an estimated development cost of $5 billion, IBM literally bet the company's future on this new architecture.

Smithsonian Institution



An IBM 360 computer, *c.* 1965. All machines in IBM's 360 line employed the same operating system, contributing to a flexibility that made it the definitive business computer of the 1960s.

The 360 was in fact an architecture, not a single machine. Designers G.M. Amdahl, F.P. Brooks, and G.A. Blaauw explicitly separated the 360 architecture from its implementation details. The 360 architecture was intended to span a wide range of machine implementations and multiple generations of machines. The first 360 models were hybrid transistor–integrated circuit machines. Integrated circuit computers are commonly referred to as third-generation computers. Key to the architecture was the operating system. OS/360 ran on all machines built to the 360 architecture—initially six machines spanning a wide range of performance characteristics and later many more machines. It had a shielded supervisory system, and it reserved certain operations as privileged in that they could be performed only by the supervisor program.

Third-generation computers

The first IBM 360 computers were delivered in 1965. The 360 architecture represented a continental divide in the relative importance of hardware and software. After the 360, computers were defined by their operating systems. The market, on the other hand, was defined by IBM. In the late 1950s and into the 1960s, it was common to refer to the computer industry as "IBM and the Seven Dwarfs," a reference to the relatively diminutive market share of its nearest rivals, Sperry Rand (UNIVAC), Control Data Corporation (CDC), Honeywell, Burroughs, General Electric (GE), RCA, and National Cash Register (NCR). During this time, IBM had some 60–70 percent of all computer sales. The 360 did nothing to lessen the giant's dominance, and, when the market did open up somewhat, it was not due to the efforts of, nor was it in favour of, the dwarfs.

TIME-SHARING AND MINICOMPUTERS

Time-sharing from Project MAC to UNIX. In 1959 Christopher Strachey in Britain and John McCarthy in the United States independently described something they called time-sharing. Meanwhile, computer pioneer J.C.R. Licklider at MIT began to promote the idea of interactive computing as an alternative to batch processing. Batch processing was the normal mode of operating computers at the time: a user handed a deck of punched cards to an operator, who fed them to the machine, and an hour or more later the printed output would be made available for pickup. Licklider's notion of interactive programming involved typing on a teletype or other keyboard and getting more or less immediate feedback from the computer on the teletype's printer mechanism or some other output device. This was how the Whirlwind computer had been operated at MIT in 1950, and it was essentially what Strachey and McCarthy had in mind at the end of the decade.

Batch processing

By November 1961 a prototype time-sharing system had been produced and tested. It was built by Fernando Corbato and Robert Jano at MIT, and it connected an IBM 709 computer with three users typing away at IBM Flexowriters. This was only a prototype for a more elaborate time-sharing system that Corbato was working on called Compatible Time-Sharing System, or CTSS. Still, Corbato was waiting for the appropriate technology to build that system. It was clear that electromechanical and vacuum tube technologies would not be adequate for the computational demands that time-sharing would place on the machines. Fast transistor-based computers were needed.

In the meantime, Licklider had been placed in charge of a U.S. government program called the Advanced Research Projects Agency (ARPA), created in response to the launch of the Sputnik satellite by the Soviet Union in 1957. ARPA researched interesting technological areas, and under Licklider's leadership it focused on time-sharing and interactive computing. With ARPA support, CTSS evolved into Project MAC, which went online in 1963. Project MAC was only the beginning. Other similar time-sharing projects followed rapidly at various research institutions, and some commercial products began to be released that also were called interactive or time-sharing.

Time-sharing represented a different interaction model, and it needed a new programming language to support it. Researchers created several such languages, most notably BASIC (Beginner's All-Purpose Symbolic Instruction Code), which was invented in 1964 at Dartmouth College, Hanover, New Hampshire, by John Kemeny and Thomas Kurtz. BASIC had features that made it ideal for time-sharing, and it was easy enough to be used by its target audience: college students. Kemeny and Kurtz wanted to open computers to a broader group of users and deliberately designed BASIC with that goal in mind.

BASIC

Time-sharing also called for a new kind of operating system. Researchers at AT&T and GE tackled the problem with funding from ARPA via Project MAC and an ambitious plan to implement time-sharing on a new computer with a new time-sharing-oriented operating system. AT&T dropped out after the project was well under way, but GE went ahead, and the result was the Multics operating system running on the GE 645 computer. GE 645 exemplified the time-shared computer in 1965, and Multics was the model of a time-sharing operating system, built to run continuously. When AT&T dropped out of the project and removed the GE machines from its laboratories, researchers at AT&T's high-tech research arm, Bell Laboratories, were upset. They felt they needed time-sharing for their work, and so two Bell Labs workers, Ken Thompson and Dennis Ritchie, wrote their own operating system. Since the operating system was inspired by Multics but would initially be somewhat simpler, they called it UNIX.

UNIX

UNIX embodied, among other innovations, the notion of pipes. Pipes allowed a user to pass the results of one program to another program for use as input. This led to a style of programming in which small, targeted, single-function programs were joined together to achieve a more complicated goal. Perhaps the most influential aspect of UNIX, though, was that Bell Labs distributed the source code (the uncompiled, human-readable form of the code that made up the operating system) freely to colleges and universities—but made no offer to support it. The freely distributed source code led to a rapid, and somewhat divergent,

evolution of UNIX. Whereas initial support was attracted by its free availability, its robust multitasking and well-developed network security features have continued to make it the most common operating system for academic institutions and World Wide Web servers.

Minicomputers. Around 1965, roughly coterminous with the development of time-sharing, a new kind of computer came on the scene. Small and relatively cheap (typically 1/10 the cost of the Big Iron machines), the new machines were stored-program computers with all the generality of the computers then in use but stripped down. The new machines were called minicomputers. (About the same time, the larger traditional computers began to be called mainframes.) Minicomputers were designed for easy connection to scientific instruments and other input/output devices, had a simplified architecture, were implemented using fast transistors, and were typically programmed in assembly language with little support for high-level languages.

The market for minicomputers evolved over time, but it was scientific laboratories that created the category. It was an essentially untapped market, and those manufacturers who established an early foothold dominated it. Only one of the mainframe manufacturers, Honeywell, was able to break into the minicomputer market in any significant way. The other main minicomputer players, such as Digital Equipment Corp. (DEC), Data General Corp., Hewlett-Packard Company, and Texas Instruments Incorporated, all came from fields outside mainframe computing, frequently from the field of electronic test equipment. The failure of the mainframe companies to gain a foothold in the field may have stemmed from their failure to recognize that minis were distinct in important ways from their smaller computers.

The first minicomputer, although it was not recognized as such at the time, may have been the MIT Whirlwind in 1950. It was designed for instrument control and had many, although not all, of the features of later minis. DEC, founded in 1957 by Kenneth Olsen and Harlan Anderson, produced one of the first minicomputers, the Programmed Data Processor, or PDP-1, in 1959. At a price of $120,000, the PDP-1 sold for a fraction of the cost of mainframe computers, albeit with vastly more limited capabilities. But it was the PDP-8, using the recently invented integrated circuit (a set of interconnected transistors and resistors on a single silicon wafer, or chip) and selling for around $20,000 (falling to $3,000 by the late 1970s), that was the first true mass-market minicomputer. The PDP-8 was released in 1965, the same year as IBM's first 360 machines.

The PDP-8

The PDP-8 was the prototypical mini. It was designed to be programmed in assembly language; it was easy, physically, logically, and electrically, to attach a wide variety of input/output devices and scientific instruments to it; and it was architecturally stripped down with little support for programming—it even lacked multiplication and division operations in its initial release.

Although the minis' early growth was due to their use as scientific instrument controllers and data loggers, their compelling feature turned out to be their approachability. After years of standing in line to use machines through intermediaries, scientists and researchers could now buy their own computer and run it themselves in their own laboratories.

The minicomputer revolution lasted about a decade. By 1975 it was coming to a close, but not because minis were becoming less attractive. The mini was about to be eclipsed by another technology: the new integrated circuits, which would soon be used to build the smallest, most affordable computers to date.

The personal computer revolution

Before 1970, computers were big machines requiring thousands of separate transistors. They were operated by specialized technicians, who were often dressed in white lab coats and commonly referred to as a computer priesthood. The machines were expensive and difficult to use. Few people came in direct contact with them, not even their programmers. The typical interaction was as follows: a programmer coded instructions and data on preformatted paper, a keypunch operator transferred the data onto punch cards, a computer operator fed the cards into a card reader, and, finally, the computer executed the instructions or stored the cards' information for later processing. Advanced installations might allow users limited interaction with the computer more directly, but still remotely, via time-sharing through the use of cathode-ray tube terminals or teletype machines.

At the beginning of the 1970s there were essentially two types of computers. There were room-sized mainframes, costing hundreds of thousands of dollars, that were built one at a time by companies such as IBM and CDC. There also were smaller, cheaper, mass-produced minicomputers, costing tens of thousands of dollars, that were built by a handful of companies, such as DEC and Hewlett-Packard, for scientific laboratories and businesses.

Still, most people had no direct contact with either type of computer, and the machines were popularly viewed as impersonal giant brains that threatened to eliminate jobs through automation. The idea that anyone would have his or her own desktop computer was generally regarded as far-fetched. Nevertheless, with advances in integrated circuit technology, the necessary building blocks for desktop computing began to emerge in the early 1970s.

THE MICROPROCESSOR

Integrated circuits. William Shockley, a coinventor of the transistor, started Shockley Semiconductor Laboratories in 1955 in his hometown of Palo Alto, California. In 1957 his eight top researchers left to form Fairchild Semiconductor Company, funded by Fairchild Camera and Instrument Company. Along with Hewlett-Packard, another Palo Alto firm, Fairchild Semiconductor was the seed of what would become known as "Silicon Valley." Historically, Fairchild will always deserve recognition as one of the most important semiconductor companies, having served as the training ground for most of the entrepreneurs who went on to start their own computer companies in the 1960s and early 1970s.

From the mid-1960s into the early '70s, Fairchild and Texas Instruments Corporation were the leading manufacturers of integrated circuits (ICs) and were continually increasing the number of electronic components embedded in a single silicon wafer, or chip. As the number of components escalated into the thousands, these chips began to be referred to as large-scale integration chips, and computers using them are sometimes called fourth-generation computers. The invention of the microprocessor was the culmination of this trend.

Fourth-generation computers

Although computers were still rare, calculators were common and accepted in offices. With advances in semiconductor technology, a market was emerging for sophisticated electronic desktop calculators. It was, in fact, a calculator project that turned into a milestone in the history of computer technology.

The Intel 4004. Intel Corporation was one of several semiconductor companies to emerge in Silicon Valley, having spun off from Fairchild Semiconductor. Intel's president, Robert Noyce, while at Fairchild, had invented planar integrated circuits, a process in which the wiring was directly embedded in the silicon along with the electronic components at the manufacturing stage. Intel had planned on focusing its business on memory chips, but a 1969 request from a Japanese company, Busicom, to design a custom chip for a calculator turned out to be a most valuable diversion. While specialized chips were effective at their given task, their small market made them expensive. Three Intel engineers—Federico Faggin, Marcian ("Ted") Hoff, and Stan Mazor—considered the request and proposed a more versatile design.

Hoff had experience with minicomputers, which could do anything the calculator could do and more. He rebelled at building a special-purpose device when the technology existed to build a general-purpose one. The general-purpose device he had in mind, however, would be a lot like a computer, and at that time computers intimidated people while calculators did not. Moreover, there was a clear and large market for calculators and a limited one for comput-

ers—and, after all, the customer had commissioned a calculator chip. Nevertheless, Hoff prevailed, and Intel proposed a design that was functionally very similar to a minicomputer. In addition to performing the input/output functions that most ICs carried out, the design would form the instructions for the IC and would help to control, send, and receive signals from other chips and devices. A set of instructions was stored in memory, and the chip could read them and respond to them. The device would thus do everything that Busicom wanted, but it would do a lot more: it was the essence of a general-purpose computer. There was little obvious demand for such a device, but the Intel team, understanding the drawbacks of special-purpose ICs, sensed that it was an economical device that would, somehow, find a market.

Intel decided to go forward with the design and named the chip the 4004, which referred to the number of features and transistors that it contained. These included memory, input/output, control, and arithmetical/logical capacities. It came to be called a microprocessor or microcomputer. It is this chip that is referred to as the brain of the personal, desktop computer—the central processing unit, or CPU. Busicom eventually sold over 100,000 calculators powered by the 4004. Busicom later also accepted a one-time payment of $60,000 that gave Intel exclusive rights to the 4004 design, and Intel began marketing the chip to other manufacturers in 1971.

The first microprocessor

The 4004 had significant limitations. As a 4-bit processor it was only capable of 2^4, or 16, distinct combinations, or "words." To distinguish the 26 letters of the alphabet and up to six punctuation symbols, the computer had to combine two four-bit words. Nevertheless, the 4004 achieved a level of fame when Intel found a high-profile customer for it: it was used on the Pioneer 10 space probe, launched on March 2, 1972.

It became a little easier to see the potential of microprocessors when Intel introduced an 8-bit processor, the 8008, in November 1972. In 1972 Intel was still a small company, albeit with two new and revolutionary products. But no one—certainly not their inventors—had figured out exactly what to do with Intel's microprocessors.

THE MICROCOMPUTER

The Altair. The advent of the microprocessor did not inspire IBM or any other large company to begin producing personal computers. Instead, the new generation of microcomputers, or personal computers, emerged from the minds and passions of electronics hobbyists and entrepreneurs. The frustration felt by engineers and electronics hobbyists who wanted easier access to computers was expressed in articles in the electronics magazines in the early 1970s.

Micro Instrumentation Telemetry Systems (MITS) had started out selling radio transmitters for model airplanes in 1968 and expanded into the kit calculator business in the early 1970s. By 1974, in need of a new product, MITS came up with the idea of selling a computer kit. The kit, containing all of the components necessary to build an Altair computer, sold for $397, barely more than the list cost of the Intel 8080 microprocessor that it used. A January 1975 cover article in *Popular Electronics* generated hundreds of orders for the kit. The machines, especially the early ones, had only limited reliability. To make them work required many hours of assembly by an electronics expert. When assembled, Altairs were blue, box-shaped machines that measured 17 inches by 18 inches by 7 inches. The only way to input programs was by setting switches on the front panel for each instruction, step-by-step. A pattern of flashing lights on the front panel indicated the results of a program. Just getting the Altair to blink its lights represented an accomplishment.

The Altair hardly represented a singular revolutionary invention, along the lines of the transistor, but it did encourage sweeping change, giving hobbyists the confidence to take the next step.

The hobby market expands. Some entrepreneurs, particularly in the San Francisco Bay area, saw opportunities to build add-on devices, or peripherals, for the Altair; others decided to design competitive hardware products. Because different machines might use different data paths, or buses, peripherals built for one computer might not work with another computer. This led the emerging industry to petition the Institute for Electrical and Electronics Engineers to select a standard bus. The resulting standard, the S-100 bus, was open for all to use and became ubiquitous among early personal computers. Standardizing on a common bus helped to expand the market for early peripheral manufacturers, spurred the development of new devices, and relieved computer manufacturers of the onerous need to develop their own proprietary peripherals.

The first bus standard

These early microcomputer companies took the first steps toward building a personal computer industry, but most of them eventually collapsed, unable to build enough reliable machines or to offer sufficient customer support. In general, most of the early companies lacked the proper balance of engineers, entrepreneurs, capital, and marketing experience. But perhaps even more significant was a dearth of software that could make personal computers useful to a larger, non-hobbyist market.

Early microcomputer software. The first programs developed for the hobbyists' microcomputers were games. Most of these were text-based adventure or role-playing games. One company created the game Micro Chess and used the profits to fund the development of an important program called VisiCalc, the industry's first spreadsheet software. These games, in addition to demonstrating some of the microcomputer's capabilities, helped to convince ordinary individuals, in particular small-business owners, that they could operate a computer.

VisiCalc

As was the case with large computers, the creation of application software for the machines waited for the development of programming languages and operating systems. Gary Kildall developed the first operating system for a microcomputer as part of a project he contracted with Intel several years before the release of the Altair. Kildall realized that a computer had to be able to handle storage devices such as disk drives, and for this purpose he developed an operating system called CP/M. Kildall's company, Digital Research, became one of the first software giants as most early microcomputer companies choose CP/M.

High-level languages were also needed in order for programmers to develop applications. Childhood friends William ("Bill") Gates and Paul Allen realized this almost immediately. When the Altair came out, Allen quit his job, and Gates dropped out of Harvard University in order to create a version of the programming language BASIC that could run on the new computer. They licensed their version of BASIC to MITS and started calling their partnership Microsoft. The Microsoft Corporation went on to develop versions of BASIC for nearly every computer that was released.

THE PERSONAL COMPUTER

Commodore and Tandy enter the field. In late 1976 Commodore Business Machines, an established electronics firm that had been active in producing electronic calculators, bought a small hobby-computer company named MOS Technology. For the first time, an established company with extensive distribution channels would be selling a microcomputer.

The next year, another established company entered the microcomputer market. Tandy Corporation, best known for its chain of Radio Shack stores, had followed the development of MITS and decided to enter the market with its own TRS-80 microcomputer, which came with 4 kilobytes of memory, a Z80 microprocessor, a BASIC programming language, and cassettes for data storage. To cut costs, the machine was built without the ability to type lower-case letters. Thanks to Tandy's chain of stores and the breakthrough price ($399 fully assembled and tested), the machine was successful enough to convince the company to introduce a more powerful computer two years later, the TRS-80 Model II, which could reasonably be marketed as a small-business computer. Tandy started selling its computers in greater volumes than most of the microcomputer start-ups, except for one.

TRS-80

Apple Computer. Like the founding of the early chip companies and the invention of the microprocessor, the story of Apple Computer is a key part of Silicon Valley

folklore. Two whiz kids, Stephen G. Wozniak and Steven P. Jobs, shared an interest in electronics. Wozniak was an early and regular participant at Homebrew Computer Club meetings, which Jobs also occasionally attended. Wozniak purchased one of the early microprocessors, the Mostek 6502 (made by MOS Technology), and used it to design a computer. When Hewlett-Packard, where he had an internship, declined to build his design, he shared his progress at a Homebrew meeting, where Jobs suggested that they could sell it together. Their initial plans were modest. Jobs figured that they could sell it for $50, twice what the parts cost them, and that they could sell hundreds of them to hobbyists. The product was actually only a printed circuit board. It lacked a case, a keyboard, and a power supply. Jobs got an order for 50 of the machines from Paul Terrell, owner of one of the industry's first computer retail stores and a frequent Homebrew attendee. To raise the capital to buy the parts they needed, Jobs sold his minibus and Wozniak his calculator. They met their 30-day deadline and continued production in Jobs's parents' garage.

The Apple I. Steven Jobs (right) and Stephen Wozniak hold an Apple I board, *c.* 1976.

After their initial success, Jobs sought out the kind of help that other industry pioneers had shunned. While he and Wozniak began work on the Apple II, he consulted with a venture capitalist and enlisted an advertising company to aid him in marketing. As a result, in late 1976 A.C. ("Mike") Markkula, a retired semiconductor company executive, helped write a business plan for Apple. lined up credit from a bank, and hired a serious businessman to run the venture. Apple was clearly taking a different path from its competitors. For instance, while Altair and the other microcomputer start-ups ran advertisements in technical journals, Apple ran an early colour ad in *Playboy* magazine. Its executive team lined up nationwide distributors. Apple made sure each of its subsequent products featured an elegant, consumer-style design. It also published well-written and carefully designed manuals to instruct consumers on the use of the machines. Other manuals explained all the technical details any third-party hardware or software company would have to know to build peripherals. In addition, Apple quickly built well-engineered products that made the Apple II far more useful: a printer card, a serial card, a communications card, a memory card, and a floppy disk. This distinctive approach resonated well in the marketplace.

In 1980 the Apple III was introduced. For this new computer Apple designed a new operating system, though it also offered a capability known as emulation that allowed the machine to run the same software, albeit much slower, as the Apple II. After several months on the market the Apple III was recalled so that certain defects could be repaired, but upon reintroduction to the marketplace it never achieved the success of its predecessor. Nevertheless, the flagship Apple II and successors in that line—the Apple II+, the Apple IIe, and the Apple IIc—made Apple into the leading personal computer company in the world. In 1980 it announced its first public stock offering, and its young founders became instant millionaires.

The graphical user interface. In 1982 Apple introduced its Lisa computer, a much more powerful computer with many innovations. The Lisa used a more advanced microprocessor, the Motorola 68000. It also had a different way of interacting with the user, called a graphical user interface (GUI). The GUI replaced the typed command lines common on previous computers with graphical icons on the screen that invoked actions when pointed to by a handheld pointing device called the mouse. The Lisa was not successful, but Apple was already preparing a scaled-down, lower-cost version called the Macintosh. Introduced in 1984, the Macintosh became wildly successful and, by making desktop computers easier to use, further popularized personal computers.

Macintosh

The Lisa and the Macintosh popularized several ideas that originated at other research laboratories in Silicon Valley and elsewhere. These underlying intellectual ideas, centred around the potential impact that computers could have on people, had been nurtured first by Vannevar Bush in the 1940s and then by Douglas Engelbart. Like Bush, who inspired him, Engelbart was a visionary. As early as 1963 he was predicting that the computer would eventually become a tool to augment human intellect, and he specifically described many of the uses computers would have, such as word processing. In 1968, as a researcher at the Stanford Research Institute (SRI), Engelbart gave a remarkable demonstration of the "NLS" (oNLine System), which featured a keyboard and a mouse, a device he had invented that was used to select commands from a menu of choices shown on a display screen. The screen was divided into multiple windows, each able to display text—a single line or an entire document—or an image. Today, almost every popular computer comes with a mouse and features a system that utilizes windows on the display.

In the 1970s some of Engelbart's colleagues left SRI for Xerox Corporation's Palo Alto (California) Research Center (PARC). In the coming years, scientists at PARC pioneered many new computer technologies. Xerox built a prototype computer with a GUI operating system called the Alto and eventually introduced a commercial version called the Xerox Star in 1981. Xerox's efforts to market this computer were a failure, and the company withdrew from the market. Apple with its Lisa and Macintosh computers and then Microsoft with its Windows operating system imitated the design of the Alto and Star systems in many ways.

PARC

Two computer scientists at PARC, Alan Kay and Adele Goldberg, published a paper in the early 1970s describing a vision of a powerful and portable computer they dubbed the Dynabook. The prototypes of this machine were expensive and resembled sewing machines, but the vision of the two researchers greatly influenced the evolution of products that today are dubbed notebook or laptop computers.

Another researcher at PARC, Robert Metcalfe, developed a network system in 1973 that could transmit and receive data at three million bits a second, much faster than was generally thought possible at the time. Xerox did not see this as related to its core business of copiers, and it allowed Metcalfe to start his own company based on the system, called Ethernet. Ethernet eventually became the technical standard for connecting digital computers together in an office environment. PARC researchers used Ethernet to connect their Altos together and to share another invention of theirs, the laser printer. PARC researchers came up with numerous innovations but left it to others to commercialize them. Today they are viewed as commonplace.

IBM's Personal Computer. The entry of IBM did more to legitimize personal computers than any event in the industry's history. By 1980 the personal computer field was starting to interest the large computer companies. Hewlett-Packard, which had earlier turned down Wozniak's proposal to enter the personal computer field, was now ready, and in January 1980 it brought out its HP-85. Hewlett-Packard's machine was more expensive ($3,250) than those of most competitors, and it used a cassette tape drive for storage while most companies were already using disk drives. Another problem was its closed architecture, which made it difficult for third parties to develop applications or software for it.

Throughout its history IBM had shown a willingness to place bets on new technologies, such as the 360 architecture. Its long-term success was due largely to its ability to innovate and to adapt its business to technological change. IBM had also innovated new marketing techniques such as the unbundling of hardware, software, and computer services. So it was not a surprise that IBM would enter the fledgling but promising personal computer business.

In fact, right from project conception, IBM took an intelligent approach to the personal computer field. It noticed that the market for personal computers was spreading rapidly among both businesses and individuals. To move more rapidly than usual, IBM recruited a team of 12 engineers to build a prototype computer. Once the project was approved, IBM picked another small team of engineers to work on the project. Philip Estridge, manager of the project, owned an Apple II and appreciated its open architecture, which allowed for the easy development of add-on products. IBM contracted with other companies to produce components for its computer and to base it on an open architecture that could be built with commercially available materials. With this plan, IBM avoided corporate bottlenecks and brought its computer to market in a year, more rapidly than competitors. Intel Corporation's 16-bit 8088 microprocessor was selected for the computer, and for software IBM turned to Microsoft Corporation. Until then the small software company had concentrated mostly on computer languages, but Gates and Allen found it impossible to turn down this opportunity. They purchased a small operating system from another company and turned it into PC-DOS (or MS-DOS, or sometimes just DOS, for disk operating system), which quickly became the standard operating system for the IBM Personal Computer. IBM had first approached Digital Research to inquire about its CP/M operating system, but Digital's executives balked at signing IBM's nondisclosure agreement. Later IBM also offered a version of CP/M but priced it higher than DOS, sealing the fate of the operating system. In reality, DOS resembled CP/M in both function and appearance, and users of CP/M found it easy to convert to the new IBM machines.

Open architecture

IBM had the benefit of its own experience to know that software was needed to make a computer useful. In preparation for the release of its computer, IBM contracted with several software companies to develop important applications. From day one it made available a word processor, a spreadsheet program, and a series of business programs.

IBM named its product the IBM Personal Computer, which quickly was shortened to the IBM PC. It was an immediate success, selling more than 500,000 units in its first two years. More powerful than other desktop computers at the time, it came with 16 kilobytes of memory (expandable to 256 kilobytes), one or two floppy disk drives, and an optional colour monitor. The giant company also took an unlikely but wise marketing approach by selling the IBM PC through computer dealers and in department stores, something it had never done before.

IBM's entry into personal computers broadened the market and energized the industry. Software developers, aware of IBM's immense resources and anticipating that the PC would be successful, set out to write programs for the computer. Even competitors benefited from the attention that IBM brought to the field, and, when they realized that they could build machines compatible with the IBM PC, the industry rapidly changed.

The market expands. *PC clones.* In 1982 a well-funded start-up firm called Compaq Computer Corporation came out with a portable computer that was compatible with the IBM PC. These first portables resembled sewing machines when they were closed and weighed about 28 pounds—at the time a true lightweight. Compatibility with the IBM PC meant that any software or peripherals, such as printers, developed for use with the IBM PC would also work on the Compaq portable. The machine caught IBM by surprise and was an immediate success. Compaq was not only successful but showed other firms how to compete with IBM. Quickly thereafter, many computer firms began offering "PC clones." IBM's decision to use off-the-shelf parts, which once seemed brilliant, had altered the company's ability to control the computer industry as it always had with previous generations of technology.

The change also hurt Apple, which found itself isolated as the only company not sharing in the standard PC design. Apple's Macintosh was successful, but it could never hope to attract the customer base of all the companies building IBM PC compatibles. Eventually, software companies began to favour the PC makers with more of their development efforts, and Apple's market share began to drop.

Microsoft's Windows. In 1985 Microsoft came out with its Windows operating system, which gave PC compatibles some of the same capabilities as the Macintosh. Year after year, Microsoft refined and improved Windows so that Apple, which failed to come up with a significant new advantage, lost its edge. IBM tried to establish yet another operating system, OS/2, but lost the battle to Gates's company. In fact, Microsoft also had established itself as the leading provider of application software for the Macintosh. Thus Microsoft dominated not only the operating system and application software business for PC-compatibles but also the application software business for the only nonstandard system with any sizable share of the desktop computer market.

Workstation computers. While the personal computer market grew and matured, a variation on its theme grew out of university labs and began to threaten the minicomputers for their market. The new machines were called workstations. They looked like personal computers, and they sat on a single desktop and were used by a single individual just like personal computers, but they were distinguished by being more powerful and expensive, by having more complex architectures that spread the computational load over more than one CPU chip, by usually running the UNIX operating system, and by being targeted to scientists and engineers, software and chip designers, graphic artists, moviemakers, and others needing high performance. Workstations existed in a narrow niche between the cheapest minicomputers and the most powerful personal computers, and each year they had to become more powerful, pushing at the minicomputers even as they were pushed at by the high-end personal computers. The most successful of the workstation manufacturers were Sun Microsystems, started by people involved in enhancing the UNIX operating system, and, for a time, Silicon Graphics, which marketed machines for video and audio editing.

Sun Microsystems

The microcomputer market now included personal computers, software, peripheral devices, and workstations. Within two decades this market had surpassed the market for mainframes and minicomputers in sales and every other measure. As if to underscore such growth, in 1996, Silicon Graphics, a workstation manufacturer, bought the star of the supercomputer manufacturers, Cray Research, and began to develop supercomputers as a sideline. Moreover, Compaq Computer Corporation—which had parlayed its success with portable PCs into a perennial position during the 1990s as the leading seller of microcomputers—bought the reigning king of the minicomputer manufacturers, Digital Equipment Corporation (DEC). Compaq announced that it intended to fold DEC technology into its own expanding product line and that the DEC brand name would be gradually phased out. Microcomputers were not only outselling mainframes and minis, they were blotting them out.

Living in cyberspace

EMBEDDED SYSTEMS

One can look at the development of the electronic computer as occurring in waves. The first large wave was the mainframe era, when many people had to share single machines. In this view, the minicomputer era can be seen as a mere eddy in the larger wave, a development that allowed a favoured few to have greater contact with the big machines. Overall, the age of mainframes could be characterized by the expression "Many persons, one computer."

The second wave of computing history was brought on by the personal computer, which in turn was made possible

by the invention of the microprocessor. The impact of personal computers has been far greater than that of mainframes and minicomputers: their processing power has overtaken that of the minicomputers, and networks of personal computers working together to solve problems can be the equal of the fastest supercomputers. The era of the personal computer can be described as the age of "One person, one computer."

Since the introduction of the first personal computer, the semiconductor business has grown into a $120 billion worldwide industry. However, this phenomenon is only partly ascribable to the general-purpose microprocessor, which accounts for about $23 billion in annual sales. The greatest growth in the semiconductor industry has occurred in the manufacture of special-purpose processors, controllers, and digital signal processors. These computer chips are increasingly being included, or embedded, in a vast array of consumer devices, including pagers, mobile telephones, automobiles, televisions, digital cameras, kitchen appliances, video games, and toys. This ongoing third wave may be characterized as "One person, many computers."

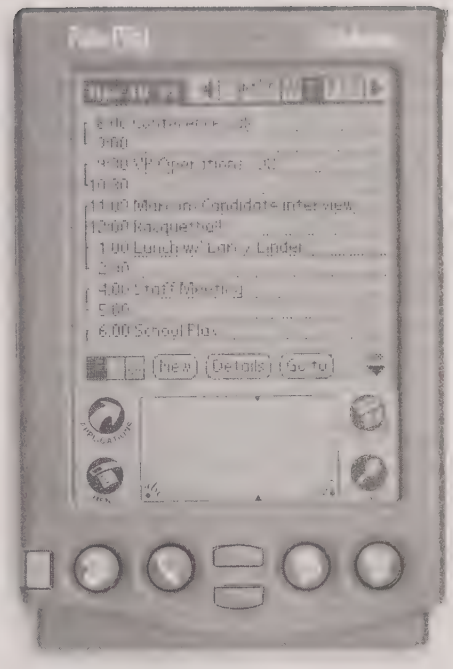
HANDHELD COMPUTERS

The popularity of the personal computer and the ongoing miniaturization of the semiconductor circuitry and other devices first led to the development of somewhat smaller, portable—or, as they were sometimes called, luggable—computer systems. The first of these, the Osborne 1, designed by Lee Felsenstein, an electronics engineer active in the Homebrew Computer Club in San Francisco, was sold in 1981. Soon, most PC manufacturers had portable models. At first these "portables" looked like sewing machines and weighed in excess of 20 pounds. Gradually they became smaller laptop-, notebook-, and then sub-notebook-sized and came with more powerful processors. These devices allowed people to use computers not only in the office or at home but while they were traveling—on airplanes, in waiting rooms, or even at the beach.

As the size of computers continued to shrink and microprocessors became more and more powerful, researchers and entrepreneurs explored new possibilities in mobile computing. In the late 1980s and early '90s, several companies came out with handheld computers, called personal digital assistants. PDAs typically replaced the cathode-ray tube screen with a more compact liquid-crystal display, and they either had a miniature keyboard or replaced the keyboard with a stylus and handwriting-recognition software that allowed the user to write directly on the screen. Like the first personal computers, PDAs were built without a clear idea of what people would do with them. In fact, people did not do much at all with the early models. To some extent, the early PDAs, made by Go Corporation and Apple Computer, Inc., were technologically premature; with their unreliable handwriting recognition, they offered little advantage over paper-and-pencil planning books.

PDAs

The potential of this new kind of device was finally realized with the release in March 1997 of Palm Computing, Inc.'s Palm Pilot, which was about the size of a deck of playing cards and sold for around $400—approximately the same price as the MITS Altair, the first personal computer sold as a kit in 1974. The Pilot did not try to replace the computer but made it possible to organize and carry information with an electronic calendar, telephone number and address list, memo pad, and expense-tracking software and to synchronize that data with a PC. The device included an electronic cradle to connect to a PC and pass information back and forth. It also featured a data-entry system, called "graffiti," which involved writing with a stylus using a slightly altered alphabet that the device recognized. Its success encouraged numerous software companies to develop applications for it. In 1998 this market heated up further with the entry of several established consumer electronics firms using Microsoft's Windows CE operating system (a stripped-down version of the Windows system) to sell handheld computer devices and wireless telephones that could connect to PCs. These small devices also often possessed a communications component and benefited from the sudden popularization of the Internet and the World Wide Web.



The Palm Pilot personal digital assistant (PDA). Introduced in March 1997, this PDA model was equipped with enough processing power to store and manipulate personal information, as well as handle the most common scheduling tasks.

THE INTERNET

The Internet grew out of funding by the U.S. Advanced Research Projects Agency (ARPA), later renamed the Defense Advanced Research Projects Agency (DARPA), to develop a communication system among government and academic computer-research laboratories. The first network component, ARPANET, became operational in October 1969. With only 15 nongovernment (university) sites included in ARPANET, the U.S. National Science Foundation decided to fund the construction and initial maintainance cost of a supplementary network, the Computer Science Network (CSNET). Built in 1980, CSNET was made available, on a subscription basis, to a wide array of academic, government, and industry research labs. As the 1980s wore on, further networks were added. In North America there were (among others): BITNET (Because It's Time Network) from IBM, UUCP (Unix-to-Unix Copy Protocol) from Bell Telephone, USENET (initially a connection between Duke University, Durham, N.C., and the University of North Carolina and still the home system for the Internet's many newsgroups), NSFNET (a high-speed National Science Foundation network connecting supercomputers), and CDNet (in Canada). In Europe several small academic networks were linked to the growing North American network.

ARPANET

All of these various networks were able to communicate with one another because of two shared protocols: the Transmission-Control Protocol (TCP), which split large files into numerous small files, or packets, assigned sequencing and address information to each packet, and reassembled the packets into the original file after arrival at their final destination; and the Internet Protocol (IP), a hierarchical addressing system that controlled the routing of packets (which might take widely divergent paths before being reassembled). In 1990 Tim Berners-Lee and others at CERN (European Organization for Nuclear Research) developed a protocol based on hypertext to make information distribution easier. In 1991 this protocol enabled the creation of the World Wide Web and its system of links among user-created pages. A team of programmers at the U.S. National Center for Supercomputing Applications, Urbana, Ill., developed a program called a browser that

TCP/IP

made it easier to use the Web, and a spin-off company named Netscape Communications Corporation was founded to commercialize that technology.

Netscape was an enormous success. The Web grew exponentially, doubling the number of users and the number of sites every few months. URLs (uniform resource locators) became part of daily life, and the use of electronic mail (e-mail) became commonplace. Increasingly, business took advantage of the Internet and adopted new forms of buying and selling in "cyberspace." (Science fiction author William Gibson popularized this term in the early 1980s.) With Netscape so successful, Microsoft and other firms developed alternative Web browsers.

Originally created as a closed network for researchers, the Internet was suddenly a new public medium for information. It became the home of virtual shopping malls, bookstores, stockbrokers, newspapers, and entertainment. Schools were "getting connected" to the Internet, and children were learning to do research in novel ways.

Ubiquitous computing

Some researchers call the trend of embedding microprocessors in a wide range of interconnected devices ubiquitous computing. Ubiquitous computing would extend the increasingly networked world and the powerful capabilities of distributed computing—*i.e.,* the sharing of computations among microprocessors connected over a network. Thanks to the increasing power and declining cost of microprocessors, researchers suggest giving computing capabilities to common office tools such as Post-it Notes, ID badges that monitor one's location, and wallboards (shared electronic "blackboards") in a manner that would render conventional forms of PCs obsolete. This vision foresees a day when it would be possible to scribble a note on a pad and have it automatically sent to appropriate recipients. Instead of a dream machine that everyone desired, microprocessors would be found wherever humans went. The technology would be invisible and natural and would respond to normal patterns of behaviour. Computers would disappear, or rather become a transparent part of the physical environment, thus truly bringing about an era of "One person, many computers."

Confucius and Confucianism

Confucianism, a Western term that has no counterpart in Chinese, is a world view, a social ethic, a political ideology, a scholarly tradition, and a way of life. Sometimes viewed as a philosophy and sometimes as a religion, Confucianism may be understood as an all-encompassing humanism that neither denies nor slights Heaven. East Asians may profess themselves to be Shintōists, Taoists, Buddhists, Muslims, or Christians, but, by announcing their religious affiliations, seldom do they cease to be Confucians.

Although often grouped with the major historical religions, Confucianism differs from them by not being an organized religion. Nonetheless, it spread to all East Asian countries under the influence of Chinese literate culture and exerted a profound influence on East Asian spiritual life as well as on East Asian political culture. Both the theory and practice of Confucianism have indelibly marked the patterns of government, society, education, and family of East Asia. It is an exaggeration to characterize traditional Chinese life and culture as Confucian, but Confucian ethical values have for well over 2,000 years served as the source of inspiration as well as the court of appeal for human interaction between individuals, communities, and nations in the Sinitic world.

Confucius

THE LIFE AND THOUGHT OF CONFUCIUS

The story of Confucianism does not begin with Confucius (Latinized form of K'ung-fu-tzu, Master K'ung; 551–479 BC). Nor was Confucius the founder of Confucianism in the sense that Buddha was the founder of Buddhism and Christ the founder of Christianity. Rather Confucius considered himself a transmitter who consciously tried to reanimate the old in order to attain the new. He proposed retrieving the meaning of the past by breathing vitality into seemingly outmoded rituals. Confucius' love of antiquity was motivated by his strong desire to understand why certain rituals, such as the ancestral cult, reverence for Heaven, and mourning ceremonies, had survived for centuries. His journey into the past was a search for roots, which he perceived as grounded in humanity's deepest needs for belonging and communicating. He had faith in the cumulative power of culture. The fact that traditional ways had lost vitality did not, for him, diminish their potential for regeneration in the future. In fact, Confucius' sense of history was so strong that he saw himself as a conservationist responsible for the continuity of the cultural values and the social norms that had worked so well for the civilization of the Chou dynasty.

The historical context. The scholarly tradition envisioned by Confucius can be traced to the sage-kings of antiquity. Although the earliest dynasty confirmed by archaeology is the Shang dynasty (18th–12th century BC), the historical period that Confucius claimed as relevant was much earlier. Confucius may have initiated a cultural process known in the West as Confucianism, but he and those who followed him considered themselves part of a tradition, later identified by Chinese historians as the *ju-chia*, "scholarly tradition," that had its origins two millennia previously, when the legendary Yao and Shun created a civilized world through moral persuasion.

The "feudal" ritual system

Confucius' hero was Chou Kung, or the Duke of Chou (d. 1094 BC), who was said to have helped consolidate and refine the "feudal" ritual system. This system was based on blood ties, marriage alliances, and old covenants as well as on newly negotiated contracts and was an elaborate system of mutual dependence. The appeal to cultural values and social norms for the maintenance of interstate as well as domestic order was predicated on a shared political vision, namely, that authority lies in universal kingship, heavily invested with ethical and religious power by the mandate of Heaven, and that social solidarity is achieved not by legal constraint but by ritual observance. Its implementation enabled the Chou dynasty to survive in relative peace and prosperity for more than five centuries.

Inspired by the statesmanship of Chou Kung, Confucius harboured a lifelong dream to be in a position to emulate the duke by putting into practice the political ideas that he had learned from the ancient sages and worthies. Although Confucius never realized his political dream, his conception of politics as moral persuasion became more and more influential.

Heaven and the mandate of Heaven

The idea of Heaven, unique in Chou cosmology, was compatible with the concept of the Lord-on-High in the Shang dynasty. The Lord-on-High may have referred to the progenitor of the Shang royal lineage so that the Shang kings could claim their position as divine descendants, as the emperors of Japan later did, but Heaven to the Chou kings was a much more generalized anthropomorphic God. They believed that the mandate of Heaven (the functional equivalent of the will of the Lord-on-High) was not constant and that there was no guarantee that the descendants of the Chou royal house would be entrusted with kingship, for "Heaven sees as the people see and Heaven hears as the people hear"; thus the virtues of the kings were essential for the maintenance of their power and authority. This emphasis on benevolent rulership, expressed in numerous bronze inscriptions, was both a reaction to the collapse of the Shang dynasty and an affirmation of a deep-rooted world view.

Partly because of the vitality of the feudal ritual system and partly because of the strength of the royal household itself, the Chou kings were able to control their kingdom for several centuries. In 771 BC, however, they were forced to move their capital eastward to present-day Lo-yang to avoid barbarian attacks from Central Asia. Real power thereafter passed into the hands of feudal lords. Since the surviving line of the Chou kings continued to be recognized in name, they still managed to exercise some measure of symbolic control. By Confucius' time, however, the feudal ritual system had been so fundamentally undermined that the political crises also precipitated a profound sense of moral decline: the centre of symbolic control could no longer hold the kingdom from total disintegration.

Confucius' response was to address himself to the issue of learning to be human. In so doing he attempted to redefine and revitalize the institutions that for centuries had been vital to political stability and social order: the family, the school, the local community, the state, and the kingdom. Confucius did not accept the status quo, which held that wealth and power spoke the loudest. He felt that virtue, both as a personal quality and as a requirement for leadership, was essential for individual dignity, communal solidarity, and political order.

The life of Confucius. Confucius' life, in contrast to his tremendous importance, seems starkly undramatic, or, as a Chinese expression has it, it seems "plain and real." The plainness and reality of Confucius' life, however, underlines that his humanity was not revealed truth but an expression of self-cultivation, of the ability of human effort to shape its own destiny. The faith in the possibility of ordinary human beings to become awe-inspiring sages and worthies is deeply rooted in the Confucian heritage, and the insistence that human beings are teachable, improvable, and perfectible through personal and communal endeavour is typically Confucian.

The perfectibility of man

Although the facts about Confucius' life are scanty, they do establish a precise time frame and historical context. Confucius was born in the 22nd year of the reign of Duke Hsiang of Lu (551 BC). The traditional claim that he was born on the 27th day of the eighth lunar month has been questioned by historians, but September 28 is still widely observed in East Asia as Confucius' birthday. It is an official holiday, "Teachers' Day," in Taiwan.

Confucius was born in Ch'ü-fu in the small feudal state of Lu in what is now Shantung Province, which was noted for its preservation of the traditions of ritual and music of the Chou civilization. His family name was K'ung and his personal name Ch'iu, but he is referred to as either K'ung-tzu or K'ung-fu-tzu (Master K'ung) throughout Chinese history. The adjectival "Confucian," derived from the Latinized Confucius, is not a meaningful term in Chinese, nor is the term Confucianism, which was coined in Europe as recently as the 18th century.

Confucius' ancestors were probably members of the aristocracy who had become virtual poverty-stricken commoners by the time of his birth. His father died when Confucius was only three years old. Instructed first by his mother, Confucius then distinguished himself as an indefatigable learner in his teens. He recalled toward the end of his life that at age 15 his heart was set upon learning. A historical account notes that, even though he was already known as an informed young scholar, he felt it appropriate to inquire about everything while visiting the Grand Temple.

Confucius had served in minor government posts managing stables and keeping books for granaries before he married a woman of similar background when he was 19. It is not known who Confucius' teachers were, but he made a conscientious effort to find the right masters to teach him, among other things, ritual and music. Confucius' mastery of the six arts—ritual, music, archery, charioteering, calligraphy, and arithmetic—and his familiarity with the classical traditions, notably poetry and history, enabled him to start a brilliant teaching career in his 30s.

The purposes of learning and teaching

Confucius is known as the first teacher in China who wanted to make education available to all men and who was instrumental in establishing the art of teaching as a vocation, indeed as a way of life. Before Confucius, aristocratic families had hired tutors to educate their sons in specific arts, and government officials had instructed their subordinates in the necessary techniques, but he was the first person to devote his whole life to learning and teaching for the purpose of transforming and improving society. He believed that all human beings could benefit from self-cultivation. He inaugurated a humanities program for potential leaders, opened the doors of education to all, and defined learning not merely as the acquisition of knowledge but also as character building.

For Confucius the primary function of education was to provide the proper way of training noblemen (*chün-tzu*), a process that involved constant self-improvement and continuous social interaction. Although he emphatically noted that learning was "for the sake of the self" (the end of which was self-knowledge and self-realization), he found public service a natural consequence of true education. Confucius confronted learned hermits who challenged the validity of his desire to serve the world; he resisted the temptation to "herd with birds and animals," to live apart from the human community, and opted to try to transform the world from within. For decades Confucius was actively involved in politics, wishing to put his humanist ideas into practice through governmental channels.

Political career and voluntary exile

In his late 40s and early 50s Confucius served first as a magistrate, then as an assistant minister of public works, and eventually as minister of justice in the state of Lu. It is likely that he accompanied King Lu as his chief minister on one of the diplomatic missions. Confucius' political career was, however, short-lived. His loyalty to the King alienated him from the power holders of the time, the large Chi families, and his moral rectitude did not sit well with the King's inner circle, who enraptured the King with sensuous delight. At 56, when he realized that his superiors were uninterested in his policies, Confucius left the country in an attempt to find another feudal state to which he could render his service. Despite his political frustration he was accompanied by an expanding circle of students during this self-imposed exile of almost 12 years. His reputation as a man of vision and mission spread. A guardian of a border post once characterized him as the "wooden tongue for a bell" of the age, sounding Heaven's prophetic note to awaken the people (*Analects,* 3:24). Indeed, Confucius was perceived as the heroic conscience who knew realistically that he might not succeed but, fired by a righteous passion, continuously did the best he could. At the age of 67 he returned home to teach and to preserve his cherished classical traditions by writing and editing. He died in 479 BC at the age of 73. According to the *Records of the Historian* 72 of his students mastered the "six arts," and those who claimed to be his followers numbered 3,000.

The Analects as the embodiment of Confucian ideas. The *Lun-yü* (*Analects*), the most revered sacred scripture in the Confucian tradition, was probably compiled by the second generation of Confucius' disciples. Based primarily on the Master's sayings, preserved in both oral and written transmissions, it captures the Confucian spirit in form and content in the same way that the Platonic dialogues embody Socratic pedagogy.

The *Analects* has often been viewed by the critical mod-

ern reader as a collection of unrelated conversations randomly put together. This impression may have resulted from the mistaken conception of Confucius as a mere commonsense moralizer who gave practical advice to students in everyday situations. If a person approaches the *Analects* as a communal memory, a literary device on the part of those who considered themselves beneficiaries of the Confucian Way to continue the Master's memory and to transmit his form of life as a living tradition, he comes close to what it has been revered for in China for centuries. Dialogues are used to show Confucius in thought and action, not as an isolated individual but as the centre of relationships. Actually the sayings of the *Analects* reveal Confucius' personality—his ambitions, his fears, his joys, his commitments, and above all his self-knowledge.

The purpose of the *Analects*

The purpose, then, in compiling these distilled statements centring on Confucius seems not to have been to present an argument or to record an event but to offer an invitation to readers to take part in an ongoing conversation. Through the *Analects* Confucians for centuries learned to reenact the awe-inspiring ritual of participating in a conversation with Confucius.

One of Confucius' most significant personal descriptions is the short autobiographical account of his spiritual development found in the *Analects:*

> At 15 I set my heart on learning; at 30 I firmly took my stand; at 40 I had no delusions; at 50 I knew the Mandate of Heaven; at 60 my ear was attuned; at 70 I followed my heart's desire without overstepping the boundaries of right. (2:4)

Confucius' life as a student and teacher exemplified his idea that education was a ceaseless process of self-realization. When one of his students reportedly had difficulty describing him, Confucius came to his aid:

> Why did you not simply say something to this effect: he is the sort of man who forgets to eat when he engages himself in vigorous pursuit of learning, who is so full of joy that he forgets his worries, and who does not notice that old age is coming on? (7:18)

Confucius was deeply concerned that the culture (*wen*) he cherished was not being transmitted and that the learning (*hsüeh*) he propounded was not being taught. His strong sense of mission, however, never interfered with his ability to remember what had been imparted to him, to learn without flagging, and to teach without growing weary. What he demanded of himself was strenuous:

> It is these things that cause me concern: failure to cultivate virtue, failure to go deeply into what I have learned, inability to move up to what I have heard to be right, and inability to reform myself when I have defects. (7:3)

What he demanded of his students was the willingness to learn: "I do not enlighten anyone who is not eager to learn, nor encourage anyone who is not anxious to put his ideas into words (7:8).

The Confucian community

The community that Confucius created was a scholarly fellowship of like-minded men of different ages and different backgrounds from different states. They were attracted to Confucius because they shared his vision and to varying degrees took part in his mission to bring moral order to an increasingly fragmented polity. This mission was difficult and even dangerous. Confucius himself suffered from joblessness, homelessness, starvation, and occasionally life-threatening violence. Yet his faith in the survivability of the culture that he cherished and the workability of the approach to teaching that he propounded was so steadfast that he convinced his followers as well as himself that Heaven was on their side. When Confucius' life was threatened in K'uang, he said:

> Since the death of King Wen [founder of the Chou dynasty] does not the mission of culture (*wen*) rest here in me? If Heaven intends this culture to be destroyed, those who come after me will not be able to have any part of it. If Heaven does not intend this culture to be destroyed, then what can the men of K'uang do to me? (9:5)

This expression of self-confidence informed by a powerful sense of mission may give the impression that there was presumptuousness in Confucius' self-image. Confucius, however, made it explicit that he was far from attaining sagehood and that all he really excelled in was "love of learning" (5:27). To him, learning not only broadened his knowledge and deepened his self-awareness but also defined who he was. He frankly admitted that he was not born endowed with knowledge, nor did he belong to the class of men who could transform society without knowledge. Rather, he reported that he used his ears widely and followed what was good in what he had heard and used his eyes widely and retained in his mind what he had seen. His learning constituted "a lower level of knowledge" (7:27), a level that was presumably accessible to the majority of human beings. In this sense Confucius was neither a prophet with privileged access to the divine nor a philosopher who had already seen the truth but a teacher of humanity who was also an advanced fellow traveler on the way to self-realization.

As a teacher of humanity Confucius stated his ambition in terms of concern for human beings: "To bring comfort to the old, to have trust in friends, and to cherish the young" (5:25). Confucius' vision of the way to develop a moral community began with a holistic reflection on the human condition. Instead of dwelling on abstract speculations such as man's condition in the state of nature, Confucius sought to understand the actual situation of a given time and to use that as his point of departure. His aim was to restore trust in government and to transform society into a moral community by cultivating a sense of humanity in politics and society. To achieve that aim, the creation of a scholarly community, the fellowship of *chün-tzu* (noblemen), was essential. In the words of Confucius' disciple Tseng-tzu, the true nobleman

The fellowship of *chün-tzu*

> must be broad-minded and resolute, for his burden is heavy and his road is long. He takes humanity as his burden. Is that not heavy? Only with death does his road come to an end. Is that not long? (8:7)

The fellowship of *chün-tzu* as moral vanguards of society, however, did not seek to establish a radically different order. Its mission was to redefine and revitalize those institutions that for centuries were believed to have maintained social solidarity and enabled people to live in harmony and prosperity. An obvious example of such an institution was the family.

It is related in the *Analects* that Confucius, when asked why he did not take part in government, responded by citing a passage from an ancient classic, the *Shu Ching* ("Classic of History"), "Simply by being a good son and friendly to his brothers a man can exert an influence upon government!" to show that what a person does in the confines of his home is politically significant (2:21). This maxim is based on the Confucian conviction that cultivation of the self is the root of social order and that social order is the basis for political stability and universal peace.

The assertion that family ethics is politically efficacious must be seen in the context of the Confucian conception of politics as "rectification" (*cheng*). Rulers should begin by rectifying their own conduct; that is, they are to be examples who govern by moral leadership and exemplary teaching rather than by force. Government's responsibility is not only to provide food and security but also to educate the people. Law and punishment are the minimum requirements for order; the higher goal of social harmony, however, can only be attained by virtue expressed through ritual performance. To perform rituals, then, is to take part in a communal act to promote mutual understanding.

The importance of filial piety

One of the fundamental Confucian values that ensures the integrity of ritual performance is *hsiao* (filial piety). Indeed, Confucius saw filial piety as the first step toward moral excellence, which he believed lay in the attainment of the cardinal virtue, *jen* (humanity). To learn to embody the family in the mind and heart is to become able to move beyond self-centredness or, to borrow from modern psychology, to transform the enclosed private ego into an open self. Filial piety, however, does not demand unconditional submissiveness to parental authority but recognition of and reverence for the source of life. The purpose of filial piety, as the ancient Greeks expressed it, is to enable both parent and child to flourish. Confucians see it as an essential way of learning to be human.

Confucians, moreover, are fond of applying the family metaphor to the community, the country, and the universe. They prefer to address the emperor as the son of

Heaven, the king as ruler-father, and the magistrate as the "father-mother official" because to them the family-centred nomenclature implies a political vision. When Confucius said that taking care of family affairs is itself active participation in politics, he had already made it clear that family ethics is not merely a private concern; the public good is realized by and through it.

Confucius defined the process of becoming human as being able to "conquer yourself and return to ritual" (12:1). The dual focus on the transformation of the self (Confucius is said to have freed himself from four things: "opinionatedness, dogmatism, obstinacy, and egoism" [9:4]) and on social participation enabled Confucius to be loyal (*chung*) to himself and considerate (*shu*) of others (4:15). It is easy to understand why the Confucian "golden rule" is "Do not do unto others what you would not want others to do unto you!" (15:23). Confucius' legacy, laden with profound ethical implications, is captured by his "plain and real" appreciation that learning to be human is a communal enterprise:

> A man of humanity, wishing to establish himself, also establishes others, and wishing to enlarge himself, also enlarges others. The ability to take as analogy of what is near at hand can be called the method of humanity. (6:30)

Confucianism

FORMATION OF THE CLASSICAL CONFUCIAN TRADITION

According to Han-fei-tzu (d. 233 BC), shortly after Confucius' death his followers split into eight distinct schools, all claiming to be the legitimate heir to the Confucian legacy. Presumably each school was associated with or inspired by one or more of Confucius' disciples. Yet the Confucians did not exert much influence in the 5th century BC. Although the mystic Yen Yüan (or Yen Hui), the faithful Tseng-tzu, the talented Tzu Kung, the erudite Tzu-hsia, and others may have generated a great deal of enthusiasm among the second generation of Confucius' students, it was not at all clear at the time that the Confucian tradition was to emerge as the most powerful one in Chinese history.

Mencius (*c.* 371–*c.* 289 BC) complained that the world of thought in the early Warring States period (475–221 BC) was dominated by the collectivism of Mo-tzu and the individualism of Yang Chu (440–*c.* 360 BC). The historical situation a century after Confucius' death clearly shows that the Confucian attempt to moralize politics was not working; the disintegration of the Chou feudal ritual system and the rise of powerful hegemonic states reveal that wealth and power spoke the loudest. The hermits (the early Taoists), who left the world to create a sanctuary in nature in order to lead a contemplative life, and the realists (proto-Legalists), who played the dangerous game of assisting ambitious kings to gain wealth and power so that they could influence the political process, were actually determining the intellectual agenda. The Confucians refused to be identified with the interests of the ruling minority because their social consciousness impelled them to serve as the conscience of the people. They were in a dilemma. Although they wanted to be actively involved in politics, they could not accept the status quo as the legitimate arena in which to exercise authority and power. In short, they were in the world but not of it; they could not leave the world, nor could they effectively change it.

Mencius: The paradigmatic Confucian intellectual. Mencius is known as the self-styled transmitter of the Confucian Way. Educated first by his mother and then allegedly by a student of Confucius' grandson, Mencius brilliantly performed his role as a social critic, a moral philosopher, and a political activist. He argued that cultivating a class of scholar-officials who would not be directly involved in agriculture, industry, and commerce was vital to the well-being of the state. In his sophisticated argument against the physiocrats (those who advocated the supremacy of agriculture), he intelligently employed the idea of the division of labour to defend those who labour with their minds, observing that service is as important as productivity. To him Confucians served the vital interests of the state as scholars not by becoming bureaucratic functionaries but by assuming the responsibility of teaching the ruling minority humane government (*jen-cheng*) and the kingly way (*wang-tao*). In dealing with feudal lords, Mencius conducted himself not merely as a political adviser but also as a teacher of kings. Mencius made it explicit that a true man cannot be corrupted by wealth, subdued by power, or affected by poverty.

Mencius' defense of scholar-officials

To articulate the relationship between Confucian moral idealism and the concrete social and political realities of his time, Mencius began by exposing as impractical the prevailing ideologies of Mo-tzu's collectivism and Yang Chu's individualism. Mo-tzu's collectivism rested on the advocacy of universal love. Mencius contended, however, that the result of the Mohist admonition to treat a stranger as intimately as one's own father would be to treat one's own father as indifferently as one would treat a stranger. Yang Chu, on the other hand, advocated the primacy of the self. Mencius contended, however, that excessive attention to self-interest would lead to political disorder. Indeed, in Mohist collectivism fatherhood becomes a meaningless concept, and so does kingship in Yang Chu's individualism.

Mencius' strategy for social reform was to change the language of profit, self-interest, wealth, and power by making it part of a moral discourse, with emphasis on rightness, public-spiritedness, welfare, and influence. Mencius, however, was not arguing against profit. Rather, he instructed the feudal lords to look beyond the narrow horizon of their palaces and to cultivate a common bond with their ministers, officers, clerks, and the seemingly undifferentiated masses. Only then, Mencius contended, would they be able to preserve their profit, self-interest, wealth, and power. He encouraged them to extend their benevolence and warned them that this was crucial for the protection of their families.

Mencius' appeal to the common bond among all people as a mechanism of government was predicated on his strong "populist" sense that the people are more important than the state and the state more important than the king and that the ruler who does not act in accordance with the kingly way is unfit to rule. Mencius insisted that an unfit ruler should be criticized, rehabilitated, or, as the last resort, deposed. Since "Heaven sees as the people see; Heaven hears as the people hear," revolution, or literally the change of the mandate, in severe cases is not only justifiable but is a moral imperative.

Mencius' "populist" conception of politics

Mencius' "populist" conception of politics was predicated on his philosophical vision that human beings can perfect themselves through effort and that human nature is good. While he acknowledged the role of biological and environmental factors in shaping the human condition, he insisted that human beings become moral simply by willing to be so. According to Mencius, willing entails the transformative moral act insofar as the propensity of humans to be good is automatically activated whenever they decide to bring it to their conscious attention.

Mencius' moral idealism

Mencius taught that all people have the spiritual resources to deepen their self-awareness and strengthen their bonds with others. Biologic and environmental constraints notwithstanding, men always have the freedom and the ability to refine and enlarge their Heaven-endowed nobility (their "great body"). The possibility of continuously refining and enlarging the self is vividly illustrated in Mencius' description of degrees of excellence:

> He who commands our liking is called good (*shan*).
> He who is sincere with himself is called true (*hsin*).
> He who is sufficient and real is called beautiful (*mei*).
> He whose sufficiency and reality shine forth is called great (*ta*).
> He whose greatness transforms itself is called sagely (*sheng*).
> He whose sageliness is beyond our comprehension is called spiritual (*shen*). (VIIB:25)

Furthermore, Mencius asserted that if men fully realize the potential of their hearts, they will understand their nature; by understanding their nature, they will know Heaven. Learning to be fully human, in this Mencian perspective, entails the cultivation of human sensitivity to embody the whole universe as one's lived experience:

> All the 10,000 things are there in me. There is no greater joy for me than to find, on self-examination, that I am true to

myself. Try your best to treat others as you would wish to be treated yourself, and you will find that this is the shortest way to humanity. (VIIA:4)

Hsün-tzu: The transmitter of Confucian scholarship. If Mencius brought Confucian moral idealism to fruition, Hsün-tzu (*c.* 300–*c.* 230 BC) conscientiously transformed Confucianism into a realistic and systematic inquiry on the human condition, with special reference to ritual and authority. Widely acknowledged as the most eminent of the notable scholars who congregated in Chi-hsia, the capital of the wealthy and powerful Ch'i state in the mid-3rd century BC, Hsün-tzu distinguished himself in erudition, logic, empiricism, practical-mindedness, and argumentation. His critique of the so-called 12 philosophers gave an overview of the intellectual life of his time. His penetrating insight into the shortcomings of virtually all the major currents of thought propounded by his fellow thinkers helped to establish the Confucian school as a forceful political and social persuasion. His principal adversary, however, was Mencius, and he vigorously attacked Mencius' view that human nature is good as naive moral optimism.

True to the Confucian and, for that matter, Mencian spirit, Hsün-tzu underscored the centrality of self-cultivation. He defined the process of Confucian education, from nobleman to sage, as a ceaseless endeavour to accumulate knowledge, skills, insight, and wisdom. In contrast to Mencius, Hsün-tzu stressed that human nature is evil. Because he saw human beings as prone by nature to pursue the gratification of their passions, he firmly believed in the need for clearly articulated social constraints. Without constraints, social solidarity, the precondition for human well-being, would be undermined. The most serious flaw he perceived in the Mencian commitment to the goodness of human nature was the practical consequence of neglecting the necessity of ritual and authority for the well-being of society.

Hsün-tzu's moral pessimism

Hsün-tzu singled out the cognitive function of the mind (human rationality) as the basis for morality. Men become moral by voluntarily harnessing their desires and passions to act in accordance with society's norms. Although this is alien to human nature, it is perceived by the mind as necessary for both survival and well-being. Like Mencius, Hsün-tzu believed in the perfectibility of all human beings through self-cultivation, in humanity and rightness as cardinal virtues, in humane government as the kingly way, in social harmony, and in education. But his view of how these could actually be achieved was diametrically opposed to that of Mencius. The Confucian project, as shaped by Hsün-tzu, defines learning as socialization. The authority of ancient sages and worthies, the classical tradition, conventional norms, teachers, governmental rules and regulations, and political officers are all important for this process. A cultured person is by definition a fully socialized member of the human community, who has successfully sublimated his instinctual demands for the public good.

Hsün-tzu's tough-minded stance on law, order, authority, and ritual seems precariously close to that of the Legalists, whose policy of social conformism was designed exclusively for the benefit of the ruler. His insistence on objective standards of behaviour may have ideologically contributed to the rise of authoritarianism, which resulted in the dictatorship of the Ch'in (221–206 BC). As a matter of fact, two of the most influential Legalists, the theoretician Han-fei-tzu from the state of Han and the Ch'in minister Li Ssu (*c.* 280–208 BC), were his pupils. Yet Hsün-tzu was instrumental in the continuation of Confucianism as a scholarly enterprise. His naturalistic interpretation of Heaven, his sophisticated understanding of culture, his insightful observations on the epistemological aspect of the mind and social function of language, his emphasis on moral reasoning and the art of argumentation, his belief in progress, and his interest in political institutions so significantly enriched the Confucian heritage that he was revered by the Confucians as the paradigmatic scholar for more than three centuries.

The paradigmatic Confucian scholar

The Confucianization of politics. The short-lived dictatorship of the Ch'in marked a brief triumph of Legalism. In the early years of the Western Han (206 BC–AD 25), however, the Legalist practice of absolute power of the emperor, complete subjugation of the peripheral states to the central government, total uniformity of thought, and ruthless enforcement of law were replaced by the Taoist practice of reconciliation and noninterference. This practice is commonly known in history as the Huang-Lao method, referring to the art of rulership attributed to the Yellow Emperor (Huang-ti) and the mysterious founder of Taoism, Lao-tzu. Although a few Confucian thinkers, such as Lu Chia and Chia I, made important policy recommendations, Confucianism before the emergence of Tung Chung-shu (*c.* 179–*c.* 104 BC) was not particularly influential. Nonetheless, the gradual Confucianization of Han politics began soon after the founding of the dynasty.

By the reign of Wu Ti (the Martial Emperor, 141–87 BC), who was by temperament a Legalist despot, Confucianism was deeply entrenched in the central bureaucracy. It was manifest in such practices as the clear separation of the court and the government, often under the leadership of a scholarly prime minister, the process of recruiting officials through the dual mechanism of recommendation and selection, the family-centred social structure, the agriculture-based economy, and the educational network. Confucian ideas were also firmly established in the legal system as ritual became increasingly important in governing behaviour, defining social relationships, and adjudicating civil disputes. Yet it was not until the prime minister Kung-sun Hung (d. 121 BC) had persuaded Wu Ti to announce formally that the *ju* school alone would receive state sponsorship that Confucianism became an officially recognized Imperial ideology and state cult.

Confucianism shaping bureaucratic procedures

As a result Confucian Classics became the core curriculum for all levels of education. In 136 BC Wu Ti set up at court five Erudites of the Five Classics (see below *The Five Classics*) and in 124 BC assigned 50 official students to study with them, thus creating a de facto Imperial university. By 50 BC enrollment at the university had grown to an impressive 3,000, and by AD 1 a hundred men a year were entering government service through the examinations administered by the state. In short, those with a Confucian education began to staff the bureaucracy. In the year 58 all government schools were required to make sacrifices to Confucius, and in 175 the court had the approved version of the Classics, which had been determined by scholarly conferences and research groups under Imperial auspices for several decades, carved on large stone tablets. (These stelae, which were erected at the capital, are today well preserved in the museum of Sian.) This act of committing to permanence and to public display the content of the sacred scriptures symbolized the completion of the formation of the classical Confucian tradition.

The Five Classics. The compilation of the *Wu Ching* (The Five Classics) was a concrete manifestation of the coming of age of the Confucian tradition. The inclusion of both pre-Confucian texts, the *Shu Ching* ("Classic of History") and the *Shih ching* ("Classic of Poetry"), and contemporary Ch'in-Han material, such as certain portions of the *Li chi* ("Record of Rites"), suggests that the spirit behind the establishment of the core curriculum for Confucian education was ecumenical. The Five Classics can be described in terms of five visions: metaphysical, political, poetic, social, and historical.

The metaphysical vision, expressed in the *I Ching* ("Classic of Changes"), combines divinatory art with numerological technique and ethical insight. According to the philosophy of change, the cosmos is a great transformation occasioned by the constant interaction of two complementary as well as conflicting vital energies, yin and yang. The universe, which resulted from this great transformation, always exhibits both organismic unity and dynamism. The nobleman, inspired by the harmony and creativity of the universe, must emulate this pattern by aiming to realize the highest ideal of "unity of man and Heaven" through ceaseless self-exertion.

Metaphysical, political, poetic, social, and historical visions

The political vision, contained in the *Shu Ching,* presents kingship in terms of the ethical foundation for a humane government. The legendary Three Emperors (Yao, Shun, and Yü) all ruled by virtue. Their sagacity, *hsiao* (filial piety), and dedication to work enabled them to create a

political culture based on responsibility and trust. Their exemplary lives taught and encouraged the people to enter into a covenant with them so that social harmony could be achieved without punishment or coercion. Even in the Three Dynasties (Hsia, Shang, and Chou) moral authority, as expressed through ritual, was sufficient to maintain political order. The human continuum, from the undifferentiated masses to the enlightened people, the nobility, and the sage-king, formed an organic unity as an integral part of the great cosmic transformation. Politics means moral persuasion, and the purpose of the government is not only to provide food and maintain order but also to educate.

The poetic vision, contained in the *Shih ching,* underscores the Confucian valuation of common human feelings. The majority of verses give voice to emotions and sentiments of communities and persons from all levels of society expressed on a variety of occasions. The basic theme of this poetic world is mutual responsiveness. The tone as a whole is honest rather than earnest and evocative rather than expressive.

The social vision, contained in the *Li chi,* shows society not as an adversarial system based on contractual relationships but as a community of trust with emphasis on communication. Society organized by the four functional occupations—the scholar, farmer, artisan, and merchant—is, in the true sense of the word, a cooperation. As a contributing member of the cooperation each person is obligated to recognize the existence of others and to serve the public good. It is the king's duty to act kingly and the father's duty to act fatherly. If the king or father fails to behave properly, he cannot expect his minister or son to act in accordance with ritual. It is in this sense that a chapter in the *Li chi* entitled the "Great Learning" specifies, "From the Son of Heaven to the commoner, all must regard self-cultivation as the root." This pervasive consciousness of duty features prominently in all Confucian literature on ritual.

The historical vision, presented in the *Ch'un-ch'iu* ("Spring and Autumn Annals"), emphasizes the significance of collective memory for communal self-identification. Historical consciousness is a defining characteristic of Confucian thought. By defining himself as a lover of antiquity and a transmitter of its values, Confucius made it explicit that a sense of history is not only desirable but is necessary for self-knowledge. Confucius' emphasis on the importance of history was in a way his reappropriation of the ancient Sinitic wisdom that reanimating the old is the best way to attain the new. Confucius may not have been the author of the *Ch'un-ch'iu,* but it seems likely that he applied moral judgment to political events in China proper from the 8th to the 5th century BC. In this unprecedented procedure he assumed a godlike role in evaluating politics by assigning ultimate historical praise and blame to the most powerful and influential political actors of the period. This practice inspired not only the innovative style of the grand historian Ssu-ma Ch'ien (*c.* 145–*c.* 85 BC), but it was also widely employed by others writing dynastic histories in Imperial China.

Tung Chung-shu: The Confucian visionary. Like Ssu-ma Ch'ien, Tung Chung-shu (*c.* 179–*c.* 104 BC) also took the *Ch'un-ch'iu* absolutely seriously. His own work, *Ch'un-ch'iu fan-lu* ("Luxuriant Gems of the Spring and Autumn Annals"), however, is far from being a book of historical judgment. It is a metaphysical treatise in the spirit of the *I Ching.* A man extraordinarily dedicated to learning (he is said to have been so absorbed in his studies that for three years he did not even glance at the garden in front of him) and strongly committed to moral idealism (one of his often-quoted dicta is "rectifying rightness without scheming for profit; enlightening his Way without calculating efficaciousness"), Tung was instrumental in developing a characteristically Han interpretation of Confucianism.

Intellectual syncretism of the Han cultural elite

Despite Wu Ti's pronouncement that Confucianism alone would receive Imperial sponsorship, Taoists, yin-yang cosmologists, Mohists, Legalists, shamanists, practitioners of seances, healers, magicians, geomancers, and others all contributed to the cosmological thinking of the Han cultural elite. Indeed, Tung himself was a beneficiary of this intellectual syncretism, for he freely tapped the spiritual resources of his time in formulating his own world view: that human actions have cosmic consequences.

Tung's inquiries on the meaning of the five agents (metal, wood, water, fire, and earth), the correspondence of human beings and the numerical categories of Heaven, and the sympathetic activation of things of the same kind, as well as his studies of cardinal Confucian values such as humanity, rightness, ritual, wisdom, and trustworthiness, enabled him to develop an elaborate world view integrating Confucian ethics with naturalistic cosmology. What Tung accomplished was not merely a theological justification for the emperor as the "Son of Heaven"; rather, his theory of mutual responsiveness between Heaven and man provided the Confucian scholars with a higher law by which to judge the conduct of the ruler.

Despite Tung's immense popularity, his world view was not universally accepted by Han Confucian scholars. A reaction in favour of a more rational and moralistic approach to the Confucian Classics, known as the "Old Text" school, had already set in before the fall of the Western Han. Yang Hsiung (*c.* 53 BC–AD 18) in the *Fa-yen* ("Model Sayings"), a collection of moralistic aphorisms in the style of the *Analects,* and the *T'ai-hsüan ching* ("Classic of the Supremely Profound Principle"), a cosmological speculation in the style of the *I Ching,* presented an alternative world view. This school, claiming its own recensions of authentic classical texts allegedly rediscovered during the Han period and written in an "old" script before the Ch'in unification, was widely accepted in the Eastern Han (AD 25–220). As the institutions of the Erudites and the Imperial university expanded in the Eastern Han, the study of the Classics became more refined and elaborate. Confucian scholasticism, however, like its counterparts in Talmudic and biblical studies, became too professionalized to remain a vital intellectual force.

Confucian scholasticism

Yet Confucian ethics exerted great influence on government, schools, and society at large. Toward the end of the Han as many as 30,000 students attended the Imperial university. All public schools throughout the land offered regular sacrifices to Confucius, and he virtually became the patron saint of education. Many Confucian temples were also built. The Imperial courts continued to honour Confucius from age to age; a Confucian temple eventually stood in every one of the 2,000 counties. As a result, the teacher, together with Heaven, Earth, the emperor, and parents, became one of the most respected authorities in traditional China.

Confucian ethics in the Taoist and Buddhist context. Incompetent rulership, faction-ridden bureaucracy, a mismanaged tax structure, and domination by eunuchs toward the end of the Eastern Han first prompted widespread protests by the Imperial university students. The high-handed policy of the court to imprison and kill thousands of them and their official sympathizers in AD 169 may have put a temporary stop to the intellectual revolt, but the downward economic spiral made the life of the peasantry unbearable. The peasant rebellion led by Confucian scholars as well as Taoist religious leaders of faith-healing sects, combined with open insurrections of the military, brought down the Han dynasty and thus put an end to the first Chinese empire. As the Imperial Han system disintegrated, barbarians invaded from the north. The plains of northern China were fought over, despoiled, and controlled by rival groups, and a succession of states was established in the south. This period of disunity, from the early 3rd to the late 6th century, marked the decline of Confucianism, the upsurge of Neo-Taoism, and the spread of Buddhism.

Fall of the Han dynasty

The prominence of Taoism and Buddhism among the cultural elite and the populace in general, however, did not mean that the Confucian tradition had disappeared. In fact, Confucian ethics was by then virtually inseparable from the moral fabric of Chinese society. Confucius continued to be universally honoured as the paradigmatic sage. The outstanding Taoist thinker Wang Pi (226–249) argued that Confucius, by not speculating on the nature of the Tao, had an experiential understanding of it superior to Lao-tzu's. The Confucian Classics remained the foundation of all literate culture, and sophisticated commen-

taries were being produced throughout the age. Confucian values continued to dominate in such political institutions as the central bureaucracy, the recruitment of officials, and local governance. The political forms of life also were distinctively Confucian. When a barbarian state adopted a Sinicization policy, notably the case of the Northern Wei (386–535), it was by and large Confucian in character. In the south systematic attempts were made to strengthen family ties by establishing clan rules, genealogical trees, and ancestral rituals based on Confucian ethics.

Revival of Confucian learning in the T'ang dynasty

The reunification of China by the Sui (581–618) and the restoration of lasting peace and prosperity by the T'ang (618–907) gave a powerful stimulus to the revival of Confucian learning. The publication of a definitive, official edition of the *Wu Ching* with elaborate commentaries and subcommentaries and the implementation of Confucian rituals at all levels of governmental practice, including the compilation of the famous T'ang legal code, were two outstanding examples of Confucianism in practice. An examination system was established based on literary competence. This system made the mastery of Confucian Classics a prerequisite for political success and was, therefore, perhaps the single most important institutional innovation in defining elite culture in Confucian terms.

The T'ang dynasty, nevertheless, was dominated by Buddhism and, to a lesser degree, by Taoism. The philosophical originality of the dynasty was mainly represented by monk-scholars such as Chi-tsang (549–623), Hsüan-tsang (602–664), and Chih-i (538–597). An unintended consequence in the development of Confucian thought in this context was the prominent rise of the metaphysically significant Confucian texts, notably *Chung yung* ("Doctrine of the Mean") and *I-chuan* ("The Great Commentary of the Classic of Changes"), which appealed to some Buddhist and Taoist thinkers. A sign of a possible Confucian turn in the T'ang was Li Ao's (d. *c.* 844) essay on "Returning to Nature" that foreshadowed features of Sung (960–1279) Confucian thought. The most influential precursor of a Confucian revival, however, was Han Yü (768–824). He attacked Buddhism from the perspectives of social ethics and cultural identity and provoked interest in the question of what actually constitutes the Confucian Way. The issue of *Tao-t'ung*, the transmission of the Way or the authentic method to repossess the Way, has stimulated much discussion in the Confucian tradition since the 11th century.

THE CONFUCIAN REVIVAL

The Buddhist conquest of China and the Chinese transformation of Buddhism, a process entailing the introduction, domestication, growth, and appropriation of a distinctly Indian form of spirituality, lasted for at least six centuries. Since Buddhist ideas were introduced to China via Taoist categories and since the development of the Taoist religion benefited from having Buddhist institutions and practices as models, the spiritual dynamics in medieval China was characterized by Buddhist and Taoist values. The reemergence of Confucianism as the leading intellectual force thus involved both a creative response to the Buddhist and Taoist challenge and an imaginative reappropriation of classical Confucian insights. Furthermore, after the collapse of the T'ang dynasty, the grave threats to the survival of Chinese culture from the Khitan, the Juchen (Chin), and later the Mongols prompted the literati to protect their common heritage by deepening their communal critical self-awareness. To enrich their personal knowledge as well as to preserve China as a civilization-state, they explored the symbolic and spiritual resources that made Confucianism a living tradition.

The Sung masters. The Sung dynasty (960–1279) was militarily weak and much smaller than the T'ang, but its cultural splendour and economic prosperity were unprecedented in human history. The Sung's commercial revolution produced flourishing markets, densely populated urban centres, elaborate communication networks, theatrical performances, literary groups, and popular religions—developments that tended to remain unchanged into the 19th century. Technological advances in agriculture, textiles, lacquer, porcelain, printing, maritime trade, and weaponry demonstrated that China excelled in the fine arts as well as in the sciences. The decline of the aristocracy, the widespread availability of printed books, the democratization of education, and the full implementation of the examination system produced a new social class, the gentry, noted for its literary proficiency, social consciousness, and political participation. The outstanding members of this class, such as the classicists Hu Yüan (993–1059) and Sun Fu (992–1057), the reformers Fan Chung-yen (989–1052) and Wang An-shih (1021–86), the writer-officials Ou-yang Hsiu (1007–72) and Su Shih (pen name of Su Tung-p'o; 1036–1101), and the statesman-historian Ssu-ma Kuang (1019–86), contributed to the revival of Confucianism in education, politics, literature, and history and collectively to the development of a scholarly official style, a way of life informed by Confucian ethics.

The Sung literati

The Confucian revival, understood in traditional historiography as the establishment of the lineage of the *Tao-hsueh* ("Learning of the Tao"), nevertheless can be traced through a line of Neo-Confucian thinkers from Chou Tun-i (1017–73) by way of Shao Yung (1011–77), Chang Tsai (1020–77), the brothers Ch'eng Hao (1032–85) and Ch'eng I (1033–1107), and the great synthesizer Chu Hsi (1130–1200). These men developed a comprehensive humanist vision in which cultivation of the self was integrated with social ethics and moral metaphysics. In the eyes of the Sung literati this new philosophy faithfully restored the classical Confucian insights and successfully applied them to the concerns of their own age.

Neo-Confucian philosophy

Chou Tun-i ingeniously articulated the relationship between the "great transformation" of the cosmos and the moral development of human beings. In his metaphysics, humanity, as the recipient of the highest excellence from Heaven, is itself a centre of cosmic creativity. He developed this all-embracing humanism by a thought-provoking interpretation of the Taoist diagram of T'ai Chi ("Great Ultimate"). Shao Yung elaborated on the metaphysical basis of human affairs, insisting that a disinterested numerological mode of analysis is most appropriate for understanding the "supreme principles governing the world." Chang Tsai, on the other hand, focused on the omnipresence of *ch'i* ("vital energy"). He also advocated the oneness of *li* ("principle"; comparable to the idea of Natural Law) and the multiplicity of its manifestations, which is created as the principle expresses itself through the "vital energy." As an article of faith he pronounced in the "Western Inscription": "Heaven is my father and Earth is my mother, and even such a small being as I finds a central abode in their midst. Therefore that which fills the universe I regard as my body and that which directs the universe I consider as my nature. All people are my brothers and sisters, and all things are my companions."

This theme of mutuality between Heaven and human beings, consanguinity between man and man, and harmony between man and nature was brought to fruition in Ch'eng Hao's definition of humanity as "forming one body with all things." To him the presence of T'ien-li ("Heavenly Principle") in all things as well as in human nature enables the human mind to purify itself in a spirit of reverence. Ch'eng I, following his brother's lead, formulated the famous dictum, "self-cultivation requires reverence; the extension of knowledge consists in the investigation of things." By making special reference to *ko-wu* ("investigation of things"), he raised doubts about the appropriateness of focusing exclusively on the illumination of the mind in self-cultivation, as his brother seems to have done. The learning of the mind as advocated by Ch'eng Hao and the learning of the principle as advocated by Ch'eng I became two distinct modes of thought in Sung Confucianism.

Chu Hsi, clearly following Ch'eng I's School of Principle and implicitly rejecting Ch'eng Hao's School of Mind, developed a pattern of interpreting and transmitting the Confucian Way that for centuries defined Confucianism not only for the Chinese but for the Koreans and the Japanese as well. If, as quite a few scholars have advocated, Confucianism represents a distinct form of East Asian spirituality, it is the Confucianism shaped by Chu Hsi. Chu Hsi virtually reconstituted the Confucian tradition, giving it new structure, new texture, and new meaning.

He was more than a synthesizer; through conscientious appropriation and systematic interpretation he gave rise to a new Confucianism, known as Neo-Confucianism in the West but often referred to as Li Hsüeh ("Learning of the Principle") in modern China.

Chu Hsi's restructuring of the scriptural tradition

The "Doctrine of the Mean" and the "Great Learning," two chapters in the *Li chi,* had become independent treatises and, together with the *Analects* and *Mencius,* had been included in the core curriculum of Confucian education for centuries before Chu Hsi's birth. But by putting them into a particular sequence, the "Great Learning," the *Analects, Mencius,* and the "Doctrine of the Mean," synthesizing their commentaries, interpreting them as a coherent humanistic vision, and calling them the Four Books, Chu Hsi fundamentally restructured the Confucian scriptural tradition. The Four Books, placed above the Five Classics, became the central texts for both primary education and civil service examinations in traditional China from the 14th century. Thus they have exerted far greater influence on Chinese life and thought in the past 600 years than any other book.

As an interpreter and transmitter of the Confucian Way Chu Hsi identified which early Sung masters belonged to the lineage of Confucius and Mencius. His judgment, later widely accepted by governments in East Asia, was based principally on philosophical insight. Chou Tun-i, Chang Tsai, and the Ch'eng brothers, the select four, were Chu Hsi's cultural heroes. Shao Yung and Ssu-ma Kuang were originally on his list, but Chu Hsi apparently changed his mind, perhaps because of Shao's excessive metaphysical speculation and Ssu-ma's obsession with historical facts.

Up until Chu Hsi's time the Confucian thinking of the Sung masters was characterized by a few fruitfully ambiguous concepts, notably the Great Ultimate, principle, vital energy, nature, mind, and humanity. Chu Hsi defined the process of the investigation of things as a rigorous discipline of the mind to probe the principle in things. He recommended a twofold method of study: to cultivate a sense of reverence and to pursue knowledge. This combination of morality and wisdom made his pedagogy an inclusive approach to humanist education. Reading, sitting quietly, ritual practice, physical exercise, calligraphy, arithmetic, and empirical observation all had a place in his pedagogical program. Chu Hsi reestablished the White Deer Grotto in present Kiangsi Province as an academy. It became the intellectual centre of his age and provided an instructional model for all schools in East Asia for generations to come.

Lu Chiu-yüan's return to Mencian moral idealism

Chu Hsi was considered the preeminent Confucian scholar in Sung China, but his interpretation of the Confucian Way was seriously challenged by his contemporary, Lu Chiu-yüan (Lu Hsiang-shan, 1139–93). Claiming that he appropriated the true wisdom of Confucian teaching by reading Mencius, Lu criticized Chu Hsi's theory of the investigation of things as fragmented and ineffective empiricism. Instead he advocated a return to Mencian moral idealism by insisting that establishing the "great body" (*i.e.,* Heaven-endowed nobility) is the primary precondition for self-realization. To him the learning of the mind as a quest for self-knowledge provided the basis upon which the investigation of things assumed its proper significance. Lu's confrontation with Chu Hsi in the famous meeting at the Goose Lake Temple in 1175 further convinced him that Confucianism as Chu Hsi had shaped it was not Mencian. Although Lu's challenge remained a minority position for some time, his learning of the mind later became a major intellectual force in Ming China (1368–1644) and Tokugawa Japan (1603–1867).

Confucian learning in Chin, Yüan, and Ming. For about 150 years, from the time the Sung court moved its capital to the South and reestablished itself there in 1127, North China was ruled by three conquest dynasties, the Liao (907–1125), Hsi Hsia (1038–1227), and Chin (1115–1234). Although the bureaucracies and political cultures of both Liao and Hsi Hsia were under Confucian influence, no discernible intellectual developments helped to further the Confucian tradition there. In the Juchen Chin dynasty, however, despite the paucity of information about the Confucian renaissance in the Southern Sung, the Chin scholar-officials continued the classical, artistic, literary, and historiographic traditions of the North and developed a richly textured cultural form of their own. Chao Ping-wen's (1159–1232) combination of literary talent and moral concerns and Wang Jo-hsü's (1174–1243) scholarship in Classics and history, as depicted in Yüan Hao-wen's (1190–1257) biographical sketches and preserved in their collected works, compared well with the high standards set by their counterparts in the South.

When the Mongols reunited China in 1279, the intellectual dynamism of the South profoundly affected the northern style of scholarship. Although the harsh treatment of scholars by the conquest Yüan (Mongol) dynasty (1206–1368) seriously damaged the well-being of the scholarly community, outstanding Confucian thinkers nevertheless emerged throughout the period. Some opted to purify themselves so that they could repossess the Way for the future; some decided to become engaged in politics to put their teaching into practice.

Hsü Heng's instruction of the Mongols

Hsü Heng (1209–81) took a practical approach. Appointed by Kublai, the Great Khan in Marco Polo's *Description of the World,* as the president of the Imperial Academy and respected as the leading scholar in the court, Hsü conscientiously introduced Chu Hsi's teaching to the Mongols. He assumed personal responsibility for educating the sons of the Mongol nobility to become qualified teachers of Confucian Classics. His erudition and skills in medicine, legal affairs, irrigation, military science, arithmetic, and astronomy enabled him to be an informed adviser to the conquest dynasty. He set the tone for the eventual success of the Confucianization of Yüan bureaucracy. In fact, it was the Yüan court that first officially adopted the Four Books as the basis of the civil service examination, a practice that was to be observed until 1905. Thanks to Hsü Heng, Chu Hsi's teaching prevailed in the Mongol period, but it was significantly simplified.

The hermit-scholar, Liu Yin (1249–93), on the other hand, allegedly refused Kublai Khan's summons in order to maintain the dignity of the Confucian Way. To him education was for self-realization. Loyal to the Chin culture in which he was reared and faithful to the Confucian Way that he had learned from the Sung masters, Liu Yin rigorously applied philological methods to classical studies and strongly advocated the importance of history. Although true to Chu Hsi's spirit, by taking seriously the idea of the investigation of things, he put a great deal of emphasis on the learning of the mind. Liu Yin's contemporary, Wu Cheng (1249–1333), further developed the learning of the mind. He fully acknowledged the contribution of Lu Chiu-yüan to the Confucian tradition, even though as an admirer of Hsü Heng he considered himself a follower of Chu Hsi. Wu assigned himself the challenging task of harmonizing the difference between Chu and Lu. As a result, he reoriented Chu's balanced approach to morality and wisdom to accommodate Lu's existential concern for self-knowledge. This prepared the way for the revival of Lu's learning of the mind in the Ming (1368–1644).

Trend toward moral subjectivity

The thought of the first outstanding Ming Confucian scholar, Hsüeh Hsüan (1389–1464), already revealed the turn toward moral subjectivity. Although a devoted follower of Chu Hsi, Hsüeh's *Records of Reading* clearly shows that he considered the cultivation of "mind and nature" to be particularly important. Two other early Ming scholars, Wu Yü-pi (1391–1469) and Ch'en Hsien-chang (1428–1500), helped to define Confucian education for those who studied the Classics not simply in preparation for examinations but as learning of the "body and mind." They cleared the way for Wang Yang-ming (1472–1529), the most influential Confucian thinker after Chu Hsi.

As a critique of excessive attention to philological details characteristic of Chu Hsi's followers, Wang Yang-ming allied himself with Lu Chiu-yüan's learning of the mind. He advocated the precept of uniting thought and action. By focusing on the transformative power of the will, he inspired a generation of Confucian students to return to the moral idealism of Mencius. His own personal example of combining teaching with bureaucratic routine, administrative responsibility, and leadership in military campaigns demonstrated that he was a man of deeds.

Despite his competence in practical affairs, Wang's primary concern was moral education, which he felt had to be grounded in the "original substance" of the mind. This he later identified as *liang-chih* ("good conscience"), by which he meant innate knowledge or a primordial existential awareness possessed by every human being. He further suggested that good conscience as the Heavenly Principle is inherent in all beings from the highest spiritual forms to grass, wood, bricks, and stone. Because the universe consists of vital energy informed by good conscience, it is a dynamic process rather than a static structure. Human beings can learn to regard Heaven and Earth and the myriad things as one body by extending their good conscience to embrace an ever-expanding network of relationships.

Wang Yang-ming's dynamic idealism

Wang Yang-ming's dynamic idealism, as Wing-tsit Chan, the dean of Chinese philosophy in North America, characterized it, set the Confucian agenda for several generations in China. His followers, such as the communitarian Wang Chi (1498–1583), who devoted his long life to building a community of the like-minded, and the radical individualist Li Chih (1527–1602), who proposed to reduce all human relationships to friendship, broadened Confucianism to accommodate a variety of life-styles.

Among Wang's critics, Liu Tsung-chou (1578–1645) was perhaps the most brilliant. His *Human Schemata* (*Jen-p'u*) offered a rigorous phenomenological description of human mistakes as a corrective to Wang Yang-ming's moral optimism. Liu's student Huang Tsung-hsi (1610–95) compiled a comprehensive biographical history of Ming Confucians based on Liu's writings. One of Huang's contemporaries, Ku Yen-wu (1613–82), was also a critic of Wang Yang-ming. He excelled in his studies of political institutions, ancient phonology, and classical philology. While Ku was well-known in his time and honoured as the patron saint of "evidential learning" in the 18th century, his contemporary Wang Fu-chih (1619–92) was discovered 200 years later as one of the most sophisticated original minds in the history of Confucian thought. His extensive writings on metaphysics, history, and the Classics made him a thorough critic of Wang Yang-ming and his followers.

The age of Confucianism: Yi-dynasty Korea, Tokugawa Japan, and Ch'ing China. Among all the dynasties, Chinese and foreign, the long-lived Yi (Chosŏn) in Korea (1392–1910) was undoubtedly the most thoroughly Confucianized. Since the 15th century, when the aristocracy (*yangban*) defined itself as the carrier of Confucian values, the penetration of court politics and elite culture by Confucianism had been unprecedented. Even today, as manifested in political behaviour, legal practice, ancestral veneration, genealogy, village schools, and student activism, the vitality of the Confucian tradition is widely felt in South Korea.

Yi T'oegye (1501–70), the single most important Korean Confucian, helped shape the character of Yi Confucianism through his creative interpretation of Chu Hsi's teaching. Critically aware of the philosophical turn engineered by Wang Yang-ming, T'oegye transmitted the Chu Hsi legacy as a response to the advocates of the learning of the mind. As a result, he made Yi Confucianism at least as much a true heir to Sung learning as Ming Confucianism was. Indeed, his *Discourse on the Ten Sagely Diagrams,* an aid for educating the king, offered a depiction of all the major concepts in Sung learning. His exchange of letters with Ki Taesung (1527–72) in the famous Four-Seven debate, which discussed the relationship between Mencius' four basic human feelings—commiseration, shame, modesty, and right and wrong—and seven emotions, such as anger and joy, raised the level of Confucian dialogue to a new height of intellectual sophistication.

In addition, Yi Yulgok's (1536–84) challenge to T'oegye's re-presentation of Chu Hsi's Confucianism, from the perspective of Chu's thought itself, significantly enriched the repertoire of the learning of the principle. The leadership of the central government, supported by the numerous academies set up by aristocratic families and by institutions such as the community compact system and the village schools, made the learning of the principle not only a political ideology but also a common creed in Korea.

In Japan, Chu Hsi's teaching, as interpreted by T'oegye, was introduced to Yamazaki Ansai (1618–82). A distinctive feature of Yamazaki's thought was his recasting of native Shintōism in Confucian terminology. The diversity and vitality of Japanese Confucianism was further evident in the appropriation of Wang Yang-ming's dynamic idealism by the samurai-scholars, notably Kumazawa Banzan (1619–91). It is, however, in Ogyū Sorai's (1666–1728) determination to rediscover the original basis of Confucian teaching by returning to its pre-Confucian sources that a true exemplification of the independent-mindedness of Japanese Confucians is found. Indeed, Ogyū's brand of ancient learning with its particular emphasis on philological exactitude foreshadowed a similar scholarly movement in China by at least a generation. Although Tokugawa Japan was never as Confucianized as Yi Korea had been, virtually every educated person in Japanese society was exposed to the Four Books by the end of the 17th century.

Developments in Japan

The Confucianization of Chinese society reached its apex during the Ch'ing (1644–1911/12) when China was again ruled by a conquest (Manchu) dynasty. The Ch'ing emperors outshone their counterparts in the Ming in presenting themselves as exemplars of Confucian kingship. They transformed Confucian teaching into a political ideology, indeed a mechanism of control. Jealously guarding their Imperial prerogatives as the ultimate interpreters of Confucian truth, they undermined the freedom of scholars to transmit the Confucian Way by imposing harsh measures, such as literary inquisition. It was Ku Yen-wu's classical scholarship rather than his insights on political reform that inspired the 18th-century evidential scholars. Tai Chen, the most philosophically-minded philologist among them, couched his brilliant critique of Sung learning in his commentary on "The Meanings of Terms in the *Book of Mencius.*" Tai Chen was one of the scholars appointed by the Ch'ien-lung emperor in 1773 to compile an Imperial manuscript library. This massive scholarly attempt, *The Complete Library of the Four Treasures,* is symbolic of the grandiose intent of the Manchu court to give an account of all the important works of the four branches of learning—the Classics, history, philosophy, and literature—in Confucian culture. The project comprised more than 36,000 volumes with comments on about 10,230 titles, employed as many as 15,000 copyists, and took 20 years to complete. The Ch'ien-lung emperor and the scholars around him may have expressed their cultural heritage in a definitive form, but the Confucian tradition was yet to encounter its most serious threat.

MODERN TRANSFORMATION

At the time of the first Opium War (1839–42) East Asian societies had been Confucianized for centuries. The continuous growth of Mahāyāna Buddhism throughout Asia and the presence of Taoism in China, shamanism in Korea, and Shintōism in Japan did not undermine the power of Confucianism in government, education, family rituals, and social ethics. In fact, Buddhist monks were often messengers of Confucian values, and the coexistence of Confucianism with Taoism, shamanism, and Shintōism actually characterized the syncretic East Asian religious life. The impact of the West, however, so fundamentally undermined the Confucian roots in East Asia that it has come to be widely debated whether or not Confucianism can remain a viable tradition in modern times.

The impact of the West

Beginning in the 19th century, Chinese intellectuals' faith in the ability of Confucian culture to withstand the impact of the West became gradually eroded. This loss of faith may be perceived in Lin Tse-hsü's (1785–1850) moral indignation against the British, followed by Tseng Kuo-fan's (1811–72) pragmatic acceptance of the superiority of Western technology, K'ang Yu-wei's (1858–1927) sweeping recommendation for political reform, and Chang Chih-tung's (1837–1909) desperate, eclectic attempt to save the essence of Confucian learning, which, however, eventually led to the anti-Confucian iconoclasm of the so-called May Fourth Movement in 1919. The triumph of Marxism-Leninism as the official ideology of the People's Republic of China in 1949 relegated Confucian rhetoric to the background. The modern Chinese intelligentsia, however, maintained unacknowledged, sometimes uncon-

scious, continuities with the Confucian tradition at every level of life—behaviour, attitude, belief, and commitment. Indeed, Confucianism remains an integral part of the psycho-cultural construct of the contemporary Chinese intellectual as well as of the Chinese peasant.

The emergence of Japan and the other newly industrialized Asian countries (South Korea, Taiwan, Hong Kong, and Singapore) as the most dynamic region of economic development since World War II has generated much scholarly interest. Labeled the "Sinitic World in Perspective," "The Second Case of Industrial Capitalism," the "Eastasia Edge," or "the Challenge of the Post-Confucian States," this phenomenon has raised questions about how the typical East Asian institutions, still suffused with Confucian values—such as a paternalistic government, an educational system based on competitive examinations, the family with emphasis on loyalty and cooperation, and local organizations informed by consensus—have adapted themselves to the imperatives of modernization.

Continuity and criticism in the late 20th century

Some of the most creative and influential intellectuals in contemporary China have continued to think from Confucian roots. Hsiung Shih-li's ontological reflection, Liang Shu-ming's cultural analysis, Fung Yu-lan's reconstruction of the learning of the principle, Ho Lin's new interpretation of the learning of the mind, T'ang Chün-i's philosophy of culture, Hsü Fu-kuan's social criticism, and Mou Tsung-san's moral metaphysics are noteworthy examples. Although some of the most articulate intellectuals in the People's Republic of China criticize their Confucian heritage as the embodiment of authoritarianism, bureaucratism, nepotism, conservatism, and male chauvinism, others in China, Taiwan, Hong Kong, Singapore, and North America have imaginatively established the relevance of Confucian humanism to China's modernization. The revival of Confucian studies in South Korea, Taiwan, Hong Kong, and Singapore has been under way for more than a generation, though Confucian scholarship in Japan remains unrivaled. Confucian thinkers in the West, inspired by religious pluralism and liberal democratic ideas, have begun to explore the possibility of a third epoch of Confucian humanism. They uphold that its modern transformation, as a creative response to the challenge of the West, is a continuation of its classical formulation and its medieval elaboration. Scholars in mainland China have also begun to explore the possibility of a fruitful interaction between Confucian humanism and democratic liberalism in a socialist context.

BIBLIOGRAPHY. The study of Confucius and Confucianism, not only as a historically significant inquiry but also as a philosophically meaningful and challenging endeavour, has come of age in the English-speaking world since the 1970s. In addition to the following bibliography, see WING-TSIT CHAN, *An Outline and an Annotated Bibliography of Chinese Philosophy,* rev. ed. (1969); and LAURENCE G. THOMPSON, *Chinese Religion in Western Languages: A Comprehensive and Classified Bibliography of Publications in English, French, and German Through 1980* (1985).

Classical age: For a major study of Confucius, see H.G. CREEL, *Confucius: The Man and the Myth* (1949, reissued 1975), also published as *Confucius and the Chinese Way* (1949, reprinted 1960). Also see HERBERT FINGARETTE, *Confucius—The Secular as Sacred* (1972), which perceives the Confucian idea of ritual as a philosophical issue; BENJAMIN I. SCHWARTZ, *The World of Thought in Ancient China* (1985), which approaches Confucius and Confucianism as a challenging intellectual enterprise in comparative studies of great civilizations; and D.C. LAU, *The Analects (Lun Yü)* (1979, reissued 1986), and *Mencius* (1970), modern translations from Chinese. I.A. RICHARDS, *Mencius on the Mind: Experiments in Multiple Definition* (1932, reissued 1983); and EZRA POUND (trans.), *The Classic Anthology Defined by Confucius* (1954, reprinted 1976), also published as *The Confucian Odes* (1959), are literary achievements. RICHARD WILHELM (trans.), *The I Ching: or, Book of Changes,* 3rd ed. (1967, reprinted 1981; originally published in German, 1924), is unsurpassed in its richness of primary sources and clarity of presentation. For scholarly interpretations of classical Confucian thought, see DONALD J. MUNRO, *The Concept of Man in Early China* (1969); HOMER H. DUBS, *Hsüntze: The Moulder of Ancient Confucianism* (1927, reissued 1966); TU WEI-MING, *Centrality and Commonality: An Essay on Chung-yung* (1976); and HELLMUT WILHELM, *Heaven, Earth, and Man in "The Book of Changes"* (1977). JOHN K. SHRYOCK, *The Origin and Development of the State Cult of Confucius* (1932, reprinted 1966), is a pioneering attempt to study Confucianism as a Chinese national institution.

The Confucian tradition: Important primary sources, all translated from Chinese, can be found in WING-TSIT CHAN (trans.), *Reflections on Things at Hand: The Neo-Confucian Anthology* (1967), writings compiled by Chu Hsi and Lü Tsu-ch'ien, *Neo-Confucian Terms Explained: The Pei-Hsi Tzu-I* (1986), writings by Ch'en Ch'un, and *Instructions for Practical Living, and Other Neo-Confucian Writings* (1963), writings by Wang Yang-ming; and JULIA CHING (ed. and trans.), *The Records of Ming Scholars* (1987), excerpts from writings by Huang Tsung-hsi. Several symposium volumes dedicated to the study of the Neo-Confucian form of life have been published, including WM. THEODORE DE BARY (ed.), *Self and Society in Ming Thought* (1970), and *The Unfolding of Neo-Confucianism* (1975); WM. THEODORE DE BARY and IRENE BLOOM (eds.), *Principle and Practicality: Essays in Neo-Confucianism and Practical Learning* (1979); HOK-LAM CHAN and WM. THEODORE DE BARY (eds.), *Yüan Thought: Chinese Thought and Religion Under the Mongols* (1982); and WM. THEODORE DE BARY and JAHYUN KIM HABOUSH (eds.), *The Rise of Neo-Confucianism in Korea* (1985). For an impressive collection of essays on Chu Hsi, see WING-TSIT CHAN (ed.), *Chu Hsi and Neo-Confucianism* (1986). Studies on major thinkers include CHI-YUN CHEN, *Hsün Yüeh (A.D. 148–209): The Life and Reflection of an Early Medieval Confucian* (1975); JAMES T.C. LIU, *Ou-yang Hsiu: An Eleventh-Century Neo-Confucianist* (1967; originally published in Chinese, 1963); A.C. GRAHAM, *Two Chinese Philosophers: Ch'êng Ming-tao and Ch'êng Yi-ch'uan* (1958, reprinted 1978); HOYT CLEVELAND TILLMAN, *Utilitarian Confucianism: Ch'en Liang's Challenge to Chu Hsi* (1982); WINSTON WAN LO, *The Life and Thought of Yeh Shih* (1974); JULIA CHING, *To Acquire Wisdom: The Way of Wang Yang-ming* (1976); TU WEI-MING, *Neo-Confucian Thought in Action: Wang Yang-ming's Youth (1472–1509)* (1976); EDWARD T. CH'IEN, *Chiao Hung and the Restructuring of Neo-Confucianism in the Late Ming* (1986); and DAVID S. NIVISON, *The Life and Thought of Chang Hsüeh-ch'eng, 1738–1801* (1966). Monographs on significant issues include WM. THEODORE DE BARY, *Neo-Confucian Orthodoxy and the Learning of the Mind-and-Heart* (1981), and *The Liberal Tradition in China* (1983); DANIEL K. GARDNER, *Chu Hsi and the Ta-hsueh: Neo-Confucian Reflection on the Confucian Canon* (1986); JOHN W. DARDESS, *Confucianism and Autocracy: Professional Elites in the Founding of the Ming Dynasty* (1983); BENJAMIN A. ELMAN, *From Philosophy to Philology: Intellectual and Social Aspects of Change in Late Imperial China* (1984); and TU WEI-MING, *Humanity and Self-Cultivation: Essays in Confucian Thought* (1979). Three studies in comparative philosophy and religion are noteworthy: DAVID E. MUNGELLO, *Leibniz and Confucianism: The Search for Accord* (1977); JULIA CHING, *Confucianism and Christianity* (1977); and JACQUES GERNET, *China and the Christian Impact: A Conflict of Cultures* (1985; originally published in French, 1982).

Modern transformation: Confucianism as it exists in the 20th century is discussed in WING-TSIT CHAN, *Religious Trends in Modern China* (1953, reissued 1969). The thesis that Confucian humanism is incompatible with modernization defined in terms of industrial capitalism was first formulated in MAX WEBER, *The Religion of China: Confucianism and Taoism* (1951; originally published in German, 1922). JOSEPH R. LEVENSON, *Confucian China and Its Modern Fate: A Trilogy,* 3 vol. in 1 (1965, reissued 1968), further develops the claim that Confucianism could not survive the challenge of Western science and technology. Critical reflections on the Weberian and Levensonian interpretation include HAO CHANG, *Liang Ch'i-ch'ao and Intellectual Transition in China, 1890–1907* (1971); CHARLOTTE FURTH (ed.), *The Limits of Change: Essays on Conservative Alternatives in Republican China* (1976); and THOMAS A. METZGER, *Escape from Predicament: Neo-Confucianism and China's Evolving Political Culture* (1977). The reasons for iconoclastic attacks on the Confucian tradition are explored in LIN YÜ-SHENG, *The Crisis of Chinese Consciousness: Radical Antitraditionalism in the May Fourth Era* (1979); and KAM LOUIE, *Critiques of Confucius in Contemporary China* (1980). Studies of modern Confucian personalities include KUNG-CHUAN HSIAO, *A Modern China and a New World: K'ang Yu-wei, Reformer and Utopian, 1858–1927* (1975); HAO CHANG, *Chinese Intellectuals in Crisis: Search for Order and Meaning (1890–1911)* (1987); JOEY BONNER, *Wang Kuo-wei: An Intellectual Biography* (1986); and GUY S. ALITTO, *The Last Confucian: Liang Shu-ming and the Chinese Dilemma of Modernity,* 2nd ed. (1986). For contemporary manifestations of the Confucian tradition, see IRENE EBER (ed.), *Confucianism: The Dynamics of a Tradition* (1986); and TU WEI-MING, *Confucian Ethics Today: The Singapore Challenge* (1984).

(T.W.-m.)

Conservation of Natural Resources

Although the idea of conservation is probably as old as the human species, the use of the word in its present context is relatively recent. Over the years conservation has acquired many connotations: to some it has meant the protection of wild nature, to others the sustained production of useful materials from the resources of the Earth. The most widely accepted definition, presented in 1980 in *World Conservation Strategy* by the International Union for Conservation of Nature and Natural Resources, is that of "the management of human use of the biosphere so that it may yield the greatest sustainable benefit while maintaining its potential to meet the needs and aspirations of future generations." The document defines the objectives of the conservation of living resources as: maintenance of essential ecological processes and life-support systems, preservation of genetic diversity, and guarantee of the sustainable use of species and ecosystems. More generally, conservation involves practices that perpetuate the resources of the Earth on which human beings depend and that maintain the diversity of living organisms that share the planet. This includes such activities as the protection and restoration of endangered species, the careful use or recycling of scarce mineral resources, the rational use of energy resources, and the sustainable use of soils and living resources.

Conservation is necessarily based on a knowledge of ecology, the science concerned with the relationship between life and the environment, but ecology itself is based on a wide variety of disciplines, and conservation involves human feelings, beliefs, and attitudes as well as science and technology.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 355.

This article is divided into the following sections:

Concepts important to conservation

THE NEED FOR NATURAL RESOURCES

Like "conservation" itself, the term natural resources has undergone an expansion in meaning as a result of a greater understanding of the relationship of human beings with the world they inhabit. Early in the 20th century natural resources were viewed primarily as sources of useful commodities. They were the raw materials in the environment that were used or capable of being used by people for some purpose: minerals and fuels, forest and grazing resources, wildlife, fisheries, and the like. In a restricted sense, the term is still used in this way. More recently, however, the concept of natural resources has been broadened to include the total natural environment—the entire surface layer of the planet—because all parts of the Earth's surface are of use and of value in that they contribute to the production of the necessities and amenities that people require or demand. Thus, when considered in this respect, the atmosphere, oceans, deserts, and polar regions have all become valuable resources that must be managed with care to provide for the future.

Primary and secondary needs. Humanity's primary needs, or natural-resource requirements for existence, include energy in the form of organic foods that are digestible, are capable of being assimilated, and contain adequate amounts of proteins, fats, carbohydrates, vitamins, and minerals; water with a relatively low content of dissolved salts and free from toxic or injurious substances; air that contains an adequate quantity of oxygen but no harmful materials; and an external source of energy for heating and cooking, as well as various materials from which clothing and shelter can be fashioned to provide warmth in cold weather and coolness during excessively hot weather. These basic human needs were supplied to mankind's earliest ancestors by wild vegetation and animal life, by springs and streams, and by the atmosphere and the Sun. Later, the discovery of fire made possible the heating of shelters and also made available a greater choice of foods—those that could be rendered more palatable by being heated.

The primary needs of people are the same today; however, with increased populations and depleted supplies of wild resources, a secondary category of needs has developed. These include those materials or energy sources needed to maintain an urban civilization. In addition to such needs, there is also a wide range of natural-resource "wants." These include the materials, experiences, or space needed to make existence more enjoyable.

Natural-resource "wants"

Agricultural and urban development. The development of agriculture enabled people to produce greater amounts of food on a more reliable basis and from smaller areas of land than previously had been possible. The direct dependence on the availability of wild food materials was lost. Greater supplies of food made it possible to provide for greater numbers of people in the agricultural regions, and these numbers soon exceeded the capacity of the original or still-existing natural environment to supply their primary needs. Thus, the first secondary needs developed—farming tools and, later, domestic animals to help use the tools more effectively and, for the latter, the food supplies necessary to keep them alive. In time, to keep the agricultural soils productive, the need for fertilizers of various kinds developed. Increasing dependence upon foods that could not be eaten raw generated the need for materials from which cooking and eating utensils could be fashioned. Thus, requirements for a wide variety of nonliving natural resources developed along with the rise of agricultural lands and settled villages.

With the growth of civilization and the concentration of people into cities, natural-resource requirements increased as secondary needs expanded. It became essential to organize and direct agriculture over large areas in order to provide for urban inhabitants. Effective transportation from farmlands to cities became essential, as did metals and all kinds of other minerals, stones, and timber suitable for the construction of buildings, ships, and vehicles; in addition, greater numbers of domestic animals (cows, hogs, sheep, etc.) were required. Human wants were further increased as the greater leisure of civilized life enabled part of the population to look beyond the problem of mere survival. Thus, a desire for contact with wild nature developed as the urban population became increasingly separated from it through city life.

Industrial and technological growth. The greatest expansion of human requirements for natural resources followed the Industrial Revolution during the latter half of the 18th and first half of the 19th centuries and the scientific and technological revolutions that succeeded it in the 20th. Resources that were of no value only a relatively few decades ago are now used—for example, beryllium for rockets and uranium for nuclear fuel. Coal, natural gas, and petroleum—resources that were scarcely used only a century ago—are now consumed in enormous quantities. The amount of food now demanded has involved an enormous input into the agricultural economy of chemical materials and sophisticated farming implements as well as an input of fuel energy that often exceeds the energy value of the food raised. Moreover, because both the demand for luxuries and the degree of wastefulness are excessive, not all consumption of resources is related to the supplying of needs.

Excessive resource demands and waste

In the confusion of needs, wants, and waste related to the current use of natural resources, it is notable that the primary human requirements are the same as they were in primitive times. It would be possible for mankind to survive, although in greatly reduced numbers, by using only wild vegetation and animal life to meet resource needs. This is because the living resources of the Earth contain all the basic requirements for human survival. The need for other resources is the result of the desire to live in greater numbers and at a standard of living considerably higher than that previously enjoyed. By reducing population growth in the future, it would be possible to enjoy a highly developed technology, a high material standard of living, and a wide range of wants and luxuries while still placing little strain upon the Earth's available resources. But, with the growing human population, with an expanding technology that becomes ever more demanding, and with the growing demands for material goods, the pressure on the Earth's natural resources increases steadily. Whether or not available quantities of these resources are sufficient to meet humanity's growing wants and needs is uncertain.

Rational use of resources. In its present usage, the conservation of natural resources includes a wide range of subsidiary concepts. One such concept is that of the rational use of the environment, which includes the preservation of certain areas or resources in an essentially undisturbed condition because they either are of scientific interest, have aesthetic appeal, or have recreational value. Preservation also serves an ecological purpose by maintaining the function of the total environment, such as the protection of forests to assure a sustained yield of water into urban reservoirs or the protection of estuaries in order to perpetuate an ocean fishery. But the preservation or the protection of natural resources is not the only concern of conservation; rational use also implies the direct use of resources for their commodity or recreational values. Thus, the harvesting of forest crops, the grazing of grasslands by livestock, the catching of fish, and the hunting of wild animals can be considered a legitimate part of the rational use of natural resources when they are carried out in such a way that the resource is perpetuated and not endangered. Such activities involve another concept, that of sustained yield. Sustained yield is the understanding that, for example, hunting and fishing should take only the annual surplus of individuals so as not to endanger the breeding stock of game animals and fishes. For another example, the cutting of trees and the grazing of grasses should remove only the annual increment or that portion realistically capable of being replaced over a period of years through the operation of natural processes with human assistance when needed.

Sustained yield

Multiple use and restoration. Also important to the concept of conservation is the recognition that natural resources have multiple values. In addition to its value as livestock forage, grass, for example, also supports wild animal life, holds soil in place, maintains the productivity of soil, keeps soil and water relationships in proper balance, and helps guarantee streamflow or yields of water to underground channels. Grasslands, moreover, have aesthetic, recreational, and scientific values. All of the many values of grassland must be considered before a decision is made to use a grassland for a particular purpose. Ideally, an area of land can serve many purposes simultaneously or sequentially; *i.e.,* can have multiple uses.

Another of the more hopeful aspects of conservation is the concept of restoration. A forest that has been cut or burned can, with care, regenerate itself. Areas that have been mined and left barren often can be revegetated with reasonable expenditures of money and effort. Depleted animal or plant populations recover their original abundance if suitably protected in an adequate habitat. The restoration of natural vegetation depends upon the ecological process of succession, in which plants with varying degrees of tolerance to extreme conditions in an environment invade a disturbed or barren area and replace one another until a stable, self-perpetuating community is achieved. Restoration is possible, however, only as long as species are protected and the genetic diversity of life is maintained. When species become extinct the restoration of past conditions becomes impossible.

THE IMPORTANCE OF CONSERVATION

Values to mankind. Conservation is essential to human survival. Because life depends upon the proper functioning of the biosphere—the relatively narrow zone of air, water, soil, and rock in which all life on Earth exists—the ultimate purpose of conservation is to maintain the biosphere in a healthy operating condition. Although it is known that green plants supply oxygen to the atmosphere, that plants and animals recycle nutrients, and that plants and animals help maintain the fertility of soils, many of the elements that contribute to the proper functioning of the biosphere have not yet been identified. Because mankind lives with such environmental uncertainties, an attitude of care and protection toward the Earth's living resources is necessary.

The role of conservation in maintaining the biosphere

Certain aspects of conservation, however, such as the prevention of pollution, have a more narrow and immediate importance. There are numerous illustrations of the serious effect of pollutants in air, water, or soil on human health and survival; for example, the accumulation of sulfur dioxide in the air of London during the 1950s led to many deaths that probably would not have otherwise occurred. The dumping of mercury-containing wastes in waters around Japan caused the death of many people and destroyed the health of others, and continuing accumulations of such toxic metals as lead, cadmium, and arsenic in air and water threaten widespread damage to human health.

Economic value. Unless viewed in terms of human survival, the economic value of conservation is sometimes difficult to demonstrate. Although the floating plants of the ocean, the microscopic phytoplankton, are of little direct economic value to people, for example, their elimination from the food chain would quickly destroy the world's marine fisheries, which are a major source of human food; in time, even the world's oxygen supply would be severely depleted.

As explained below, much of the apparent conflict in the economics of conservation results from the difference between short-term or individual interests and the long-term interests of groups or of all mankind. The long-term economic community benefits to be derived from stable and productive farmlands and forests are considerable when compared with farms that are exploited, eroded, and abandoned or with forests that are cut, burned, and allowed to deteriorate. Short-term economic considerations, however, may lead individuals or communities to exploit their farms and forests for maximum profit at minimum cost and then move on, leaving the deteriorated lands behind.

Aesthetic and recreational value. Appreciation of wild nature as a source of aesthetic pleasure and the use of wildlands and wild-animal resources for recreational enjoyment have long been recognized as among the more important values of conservation. Outdoor-based recreational activities, such as fishing, hunting, boating, swimming, picnicking, sunbathing, hiking, and skiing, are related to the continued existence of natural or near-natural environments as the sites for these activities. Although it is

The appreciation of wild nature

almost impossible to evaluate aesthetic and recreational values in terms of their psychological or sociological importance, because they may vary from one culture to another, evidence indicates that, as personal affluence and the freedom from the sheer struggle for survival increase, the demand for outdoor recreation and outdoor space also increases. Even in the absence of government activity, it has become financially attractive for private investors to provide facilities and opportunities that exploit outdoor recreational resources.

Scientific value. Conservation is also of great scientific value. Because relatively little is known about the past, present, and possible future of the biosphere, natural outdoor laboratories, including areas of undisturbed nature, must be maintained in order to conduct the studies needed to acquire knowledge. Moreover, there are many natural resources with undiscovered scientific and technological values. If, for example, all apparently worthless rosy periwinkle plants had been destroyed, an important drug used in treating leukemia would not have been discovered. Because each wild plant and animal contains a storehouse of genetic and biochemical information, the loss of a single species might result in the loss of information that could ultimately have great value for mankind's welfare or survival.

Conflicting attitudes and issues. Although the importance of conservation may seem obvious, most of the world's people live too close to the margin of existence to exercise concern for anything more than their immediate survival and well-being. Planning for the future becomes difficult when the present itself is in doubt, and activities that could help tomorrow's generations may seem quixotic to those for whom survival is at stake. Thus, while conservation has made great strides in some areas of the world, it is still too soon for people to have any feeling of security about the future of the environment.

Short-term versus long-term views. It is often regarded as essential to the survival or the enrichment of an individual or a group to use resources in such a way as to realize immediate gains or profits. Such activities, however, may impair the future productivity of an area of land, exterminate a species, or destroy the usefulness of a site for any other purpose. In such a situation the short-term, private view conflicts with the long-term, public view. Though many would argue that the public view should be more conservation oriented, emphasizing proper safeguards to prevent deterioration of the environment, there are, nevertheless, times when governments take the short-term view in the face of real or imagined economic or political crises; they may, for example, authorize widespread destruction of resources as a temporary expedient to achieve a military goal or to strengthen the public treasury. But crises will tend to become self-perpetuating if the destruction of resources weakens the country ecologically and economically. Thus, continued, unrestricted population growth in a country poorly equipped to manage its natural resources creates a continuing sense of crisis, because ever-expanding immediate needs are commonly met at the cost of future productivity and environmental stability.

Conflicting governmental roles

As long as human populations were small and the pressures upon the environment were limited, conflicts between long-term and short-term interests made little difference. Deteriorated lands could be abandoned and new lands found because there was sufficient time to permit natural repair of environmental damage. Presently, however, with great and increasing numbers of people on a planet of limited capacity, conservationists are insisting that the difference between short- and long-term points of view be resolved in favour of actions that guarantee the survival of mankind.

Technological issues. Technological progress is another important reason for many conflicts in matters pertaining to conservation. Although technology can be a boon, it can also be poorly related to environmental realities. Through the use of technology great environmental changes can quickly be brought about. Although these changes are usually intended to be beneficial, they frequently occur in natural environments in which all things are ecologically related to one another. As a consequence, the changes may produce side effects that were not anticipated or that were discounted as being of little importance, thereby disrupting other human activities or the environment as a whole. Examples of such situations include the polluting effects of certain industries or the spread of waterborne diseases following the construction of major irrigation projects.

Use of global resources. A further area of conflict lies in attitudes toward resources that are held in common, such as the atmosphere and oceans. In instances in which the use of such resources is essentially free to the user, and the power to control use does not rest with any recognized authority, the resource often deteriorates. Although each fisherman may feel that his individual activities have very little effect on the resources of the ocean, the effect of the activities of all fishermen may threaten the existence of those resources. Similarly, each automobile driver does not feel that he is contributing much to the pollution of the global atmosphere, but all automobiles throughout the world contribute a total level of pollution that most critics feel cannot long be tolerated. When such situations exist, a recognized controlling authority is usually seen to be necessary.

The history of conservation

EARLY PRACTICES

For most of its history, the human species has lived by hunting animals and gathering wild plant foods. By extrapolation from studies of peoples who today live by such methods, it can be suggested that the relationship of hunter-gatherers with nature was relatively benign. It can also be suggested that people acquire and pass on through oral tradition a remarkable amount of knowledge about the plants and animals with which they associate and on which they depend. A number of breakthroughs in modern medicine, for example, have come from observing the therapeutic uses that traditional tribal cultures make of various wild plants. It is also known, however, that in prehistoric times people did modify their natural environment. Many grassland areas throughout the world have come to exist because people used fire as an aid to hunting or to modify vegetation to make it more suitable to their needs. Early hunting and gathering cultures contributed to the extermination of some animal species, although this seems to have been more of an exception than a general practice. For the most part, early humanity lived in an equable balance with the natural environment, if for no other reason than necessity. If they had done serious damage, people could not have survived.

Early mankind and the environment

Agriculture has been practiced only during the last 10,000–12,000 years, and urban civilization has been in existence only during the last 6,000 years. With urban life came pressure upon the natural environment and upon agricultural lands that was sometimes excessive. In the Asian homelands of Western agriculture there is widespread evidence of serious soil erosion during ancient times. Destruction of vegetation and the spread of deserts followed the rise of early urban civilizations in many areas of the Middle East and North Africa.

Ancient conservation practices. Certain conservation practices did develop in early civilizations, however. Some species of animals were protected by religious taboos; religious sanctions prevented the destruction of forest groves and sacred mountains. The use of organic fertilizer to maintain soil fertility is found among many more recent primitive peoples and has had a long history in Western agriculture. The Bible is filled with various injunctions governing the use of land and resources that have a conservation function. Civilizations such as those of the Phoenicians and the Incas developed sophisticated techniques of terracing to prevent soil erosion on hillsides and to make more effective use of water for irrigation. The earliest civilizations also show evidence of the creation of reserves or parks to protect wildlife or natural areas. Although they were hunting preserves for the use of royalty, they also served a conservation function.

As civilization developed, the accumulation of human experience led to increasingly sound land-use practices, evidence of which is found in the written descriptions of

Early development of sound land use

Roman agriculture and, later, in the well-tended irrigated fields and gardens developed during the height of Muslim culture. The agricultural landscapes of preindustrial western Europe, Japan, and China reflected great skill in the conservation of soil resources. Irrigated lands in the Nile Valley and volcanic soils in tropical Southeast Asia have been kept fertile and productive over thousands of years.

In preindustrial times, however, concern over wild nature was not widespread, largely because it was viewed as vast and inexhaustible relative to the domain, the numbers, and the power of human beings. This view was a justifiable one, because the 500,000,000 people who inhabited the world in 1600 lacked the energy sources and the machinery to effect great environmental changes. Moreover, most of the Earth's surface was sparsely settled.

Conservation during and following the age of exploration. Starting with the voyages of discovery in the 15th century, the influence of European culture was spread over the world. By the 17th century Europeans were equipped with an increasingly powerful technology and a growing ability to modify large areas of the Earth and to subdue less aggressive peoples. During this period the attitudes of explorers and colonists were oriented more toward immediate personal aggrandizement of the lands they visited and settled than toward any concern for the long-term health and productivity of the newly discovered countries. Soil erosion as well as the destruction of natural vegetation and wildlife accompanied the spread of European colonization in the Americas, Australia, and Africa. Nevertheless, during the same period, various conservation ideas and practices were being promoted. Forest conservation, for example, developed sound beginnings in 17th-century England and France, in part because of the disappearance of natural forests as a result of the increasing demand for wood fuel for industrial uses. As early as the 18th century in eastern North America, such men as Thomas Jefferson already had sound ideas for land management and conservation, and a general interest in and concern for wildlife was developing.

Environmental depredations in the 19th century

The 19th century, however, witnessed unusually severe environmental depredations. In Australia, for example, livestock populations were allowed to increase to levels far above what the natural forage could support. Although millions of animals died during drought periods, the process of overforaging damaged the range lands to such a degree that they have not yet recovered. In southern Africa many forms of wildlife were hunted to extinction, and most of the larger mammals were reduced to numbers that endangered their survival. It was in North America, however, that the changes were most dramatic. The great herds of wildlife that inhabited the plains and prairies vanished as the numbers of bison, elk, antelope, and deer were reduced by hunters. Even the larger predatory animals were nearly exterminated, and some of them—varieties of grizzly bear, cougar, and wolf—subsequently became extinct. Many types of birds that once had occurred in great abundance—*e.g.*, the passenger pigeon, Carolina parakeet, and heath hen—were wiped out. Logging and fires combined to menace the once luxurious forests of New England, the states surrounding the Great Lakes, and the South. The grasslands were overgrazed, and in some areas such as California native vegetation was eliminated over most of its range and replaced by species of European and Asian origin. It was in the West Indies and other islands throughout the world that changes were most marked. Native plant and animal species were eradicated and replaced by exotic invaders. By contrast, in the long-settled areas of Europe and Asia, changes were much less marked, as conservation-oriented systems of land management persisted.

Rise of the modern conservation movement. It could have been predicted that the modern conservation movement would have its beginnings not in the settled lands of the Old World but in those areas of the New World where, within the memory of a single generation, there had been extreme changes in the landscape and in the abundance of wildlife. The reaction to the destruction of natural resources in those areas precipitated the formation and growth of the conservation movement. As early as 1832, George Catlin, a U.S. artist and author, first proposed the idea of national parks encompassing major areas in which Indians and wild country could both be preserved. In the same decade the botanist William Bartram and the ornithologist John James Audubon were arousing an interest in wildlife and its conservation. A little later, the writers Ralph Waldo Emerson and Henry David Thoreau presented strong arguments concerning the importance of the continued survival of wild nature to the psychological well-being of mankind. Thoreau became one of the first literary advocates of wilderness conservation. The first textbook on conservation, *Man and Nature,* by George Perkins Marsh, appeared in the 1860s. In the same period the author and naturalist John Muir settled in California and became a leading advocate of wilderness preservation.

The establishment of national parks

In 1872 the U.S. Congress proclaimed the Yellowstone region of Wyoming as a national park and also established for the first time a national-government role in the protection and administration of such areas. In 1891 the first of the U.S. forest reserves, forerunners of the system of national forests, was proclaimed in the area around Yellowstone National Park.

Conservation as a national movement owes much to Pres. Theodore Roosevelt and his immediate advisers. Roosevelt's chief forester, Gifford Pinchot, is credited with having first used the term "conservation" in its present context. Pinchot was to become the leader of the nation's Forest Service and, along with Roosevelt, he advocated a utilitarian, "wise use" approach to conservation. In this, Pinchot and Roosevelt came into conflict with representatives of another school of thought, called preservationist and represented by Muir, over the building of a dam in the canyon of the Tuolumne River in Yosemite National Park, to provide a water supply for San Francisco. The philosophy of Roosevelt and Pinchot prevailed and the dam was built, but Muir's ideas lived on with the Sierra Club, of which he was a founder.

RECENT HISTORY

The recent history of conservation has been marked by a great expansion of government roles in protecting the environment and by a growth of public interest in and support for this process. National-park systems, dedicated to the preservation of wild nature and to the provision of outdoor recreation space, have grown rapidly, and national-forest systems, dedicated to the multiple use of wild-land resources, have also become firmly established. In the United States the conservation of wildlife became a cause of national interest and led to the establishment of a far-ranging system of wildlife refuges and the gradual restoration of most wild animal species to levels approaching, in some cases exceeding, their primitive abundance. On private lands, however, and on government or public-domain lands not specifically reserved as national forests, parks, or refuges, deterioration continued, reaching a peak in the 1930s, when it became widely recognized that those range lands in the public domain had been disastrously overgrazed and that many privately owned farmlands had been depleted or exhausted. Firm control over the management of lands in the public domain and federal intervention to establish soil conservation on privately owned lands were accepted as appropriate activities for the national government.

Spread of modern conservation practices. Conservation ideas spread widely, being most readily accepted by those countries that had experienced sudden environmental changes. By the 1920s national parks were to be found on all continents. In 1924 the Soviet Union established the first of its now extensive system of natural reserves (*zapovedniki*). Conservation-oriented management of forest lands, which grew more from its origins in Europe than from practices in the United States, also became more widely accepted throughout the world. The scientific basis for the management of wild grazing lands for the sustained production of forage for livestock was established in U.S. national forests in 1913 and soon spread to other countries. Aldo Leopold in the United States, in 1933, wrote a textbook on game management, in which the conservation and management of wild animal life for such recreational purposes as sport hunting and fishing and for

direct commodity values on a sustained basis received particular emphasis. Leopold's work drew heavily on earlier studies of animal ecology by Charles Sutherland Elton in England; in fact, the establishment in Europe of wildlife reserves and protective laws as well as the managing of lands to produce sustained crops of wildlife long preceded even Elton's work. Subsequently, the management of wild animals in extensive wilderness areas made major strides in Africa, which possesses unusual wildlife resources, and in the Soviet Union, which retains large areas of wildland.

The production of sustained "crops" of wildlife

New conservation problems and approaches. After World War II the field of conservation expanded as new problems arose and as some older approaches proved to have been inadequate. With growing populations and increasing pressures on land and resources, planning for their use by taking into account only a single factor or a few factors at the most was found to be highly unsatisfactory. One such instance was the development of more effective synthetic pesticides for use in the control of disease-carrying insects as well as those that prey most heavily upon agricultural crops. The initial results were remarkable. In some countries, where the insecticide DDT was used to control malaria-bearing mosquitoes, the disease was reduced from being an important cause of human illness and mortality to a low and manageable level. Similarly, agricultural pests were drastically reduced, and crop yields soared in many regions. Eventually, however, it was discovered that the pesticides had unexpected and severe consequences on the environment, and by the 1970s their use anywhere for any purpose was open to serious debate.

All forms of pollution also became a matter of major significance as populations and industrial activities increased after World War II. Air in major cities became toxic; water supplies in many heavily populated areas were contaminated. Nuclear radiation had become a major cause for concern by the 1950s and early 1960s when it was found that radioactive materials from test explosions of atomic and hydrogen bombs spread throughout the entire biosphere instead of being confined to the immediate areas in which the tests were conducted.

In response to the need for a much more integrated approach to environmental problems and to natural-resource management than existed at the time, many countries established ministries for the environment or their equivalent, and in 1969 the United States, by the National Environmental Policy Act, established a national Council on Environmental Quality to oversee and help coordinate those activities of government departments that could have an effect upon the environment.

International environmental problems

By 1970, however, the problems of the environment had become international in scope. The oceans were seriously polluted, and no single country could control the situation. Pesticides and other toxic materials spread by air and water currents throughout the world were causing or threatening to cause environmental damage everywhere. But the need for an international approach to conservation problems found most nations generally unprepared to cope with the situation. Conservation-oriented recommendations aimed at controlling the use of radioactive materials, heavy metals, toxic pesticides, or the dumping of petroleum at sea could not be enforced internationally. The need to regulate the exploitation of marine resources was widely acknowledged, but such regulation was ineffective without an empowered international authority.

In recognition of these problems many international conferences were held, new treaties and conventions were proposed, and the need for regulatory power over the environment at an intergovernmental level was stated frequently. The World Health Organization and the World Meteorological Organization began a global program to monitor pollution levels. The United Nations Educational, Scientific and Cultural Organization (UNESCO) launched a major scientific program directed toward the problems of "Man and the Biosphere," and an international conference on environmental problems was held in Stockholm in June 1972. Following the conference, the United Nations General Assembly established the UN Environment Programme (UNEP) to act on the recommendations of the Stockholm meeting. The UNEP surveyed the status of many aspects of the world's environment and natural resources, subsequently publishing its findings in numerous reports. In 1980 the International Union for Conservation of Nature and Natural Resources, with the support of UNEP and the World Wildlife Fund, published *World Conservation Strategy.* This document, which presented worldwide strategies for the rational use of resources, has served as the basis for many national conservation plans. But many critics feared that, until the nations of the world were more willing to delegate greater authority to international organizations and to support them financially, little progress toward the solution of global problems could be expected. In existing conditions of international relations, this left each nation to attempt to do what it could within its own boundaries.

Types of natural resources

In classifying natural resources it has been traditional to distinguish between those that are renewable and those that are nonrenewable. The former were once considered to be the living resources—*e.g.,* forests, wildlife, and the like—because of their ability to regenerate through reproduction. The latter were considered to be nonliving mineral or fuel resources, which, once used, did not replace themselves. In practice this separation is not entirely satisfactory, for reasons that will be dealt with in a later section. There are, nevertheless, certain aspects of conservation that apply specifically to nonliving resources:

1. Beneficiation is the upgrading of a resource that was once too uneconomical to develop. It usually depends upon technological improvements, such as those that make possible the concentration of a dispersed fuel or mineral so that it can be more easily handled, transported, or processed.
2. Maximization is the aggregate of those measures that avoid waste and increase the production of a resource.
3. Substitution involves the use of common resources in place of rare ones, as, for example, the use of aluminum in place of less abundant copper for a variety of products.
4. Allocation is the determination of the most appropriate use for a resource and the assignment of the resource to that purpose. In market economies allocation is usually controlled by the pricing mechanism: if the demand for a particular purpose is high, then the price of a resource to be used for that purpose will also be high; this high price will in turn make it more likely that the resource will be used mostly for that purpose. In government-controlled economies a resource may be reserved only for what are considered to be its most important uses.
5. Recycling, one of the most promising methods for conservation of mineral resources, involves the concentration of used or waste materials, their reprocessing (if this is required), and their subsequent reutilization in place of new materials. If carried out in an organized and consistent manner, recycling can greatly reduce the drain on supplies of minerals. It is also appropriate for products derived from living resources, such as the reuse of wood and paper as well as the reclamation of organic fertilizers from sewage.

Because all natural resources form a continuum, from those that are most renewable in the short term to those that are least renewable, they do not readily lend themselves to a single system of classification. It is useful, therefore, to examine the various types of natural resources in relation to their cycling time; *i.e.,* the length of time required to replace a given quantity of a resource that has been utilized with an equivalent quantity in a similarly useful form. From this point of view, renewable resources can be considered as those with short cycling times and nonrenewable resources as those with very long cycling times. Any resource can be nonrenewable, however, if the demand and rate of utilization exceed its cycling capacity.

The concept of cycling time

Two kinds of natural resources, pasture grass and coal, can be used to illustrate the concept of cycling time. When grass is grazed by livestock or mowed, a crop of it is removed. If provision is made to protect the fertility and structure of the soil and to leave enough seed or adequate roots and vegetative parts to produce new growth, then a

grass crop can be removed from a pasture each year for an indefinite period of time. Removal of one year's crop does not diminish the supply available for the next year if the land is cared for properly. The cycling time for this resource may be one year in areas in which climate limits growth, or it may be less than a year if growth can be continuous.

By contrast, the coal resources of the Earth were built up over millions of years. Most were laid down during the Carboniferous Period of geologic time (from 345,000,000 to 280,000,000 years ago), when climates were warm. Extensive swamp forests covered large areas of the Earth, and conditions were favourable for plant debris to accumulate in extensive deposits without decomposing and breaking down organically. Subsequently, heat and pressure generated by the deposition of other materials on top of the organic debris and by movements of the Earth's crust transformed the plant remains into coal. Organic debris is still being produced in swamps and marshes, and over millions of years this, too, could become transformed into coal. The time scale is so great, however, that, for human purposes, coal can be considered as a nonrenewable resource. Thus, only the supplies presently available in the Earth's crust can be counted on for future use.

RENEWABLE RESOURCES

Plants and animals. The most clearly recognizable renewable resources are those consisting of, or produced by, living things. Agricultural crops, animal forage, forest crops, wild and domestic animals—all can continue to reproduce and regenerate their populations as long as environmental conditions remain favourable and an adequate seed source or breeding stock is maintained. Moreover, all can be cropped or harvested without diminishing their supply, provided that the cropping does not exceed the reproduction or growth rate. If it does, the resources will be depleted; and, if the rate of cropping continuously exceeds the rate of replacement or regrowth, the resource ceases to be renewable, and the species involved are reduced to the point of extinction. A renewable resource thus can be said to be "mined"—that is, it is removed at a rate that does not permit renewal. The renewability of a living resource is further endangered if the environment required by that resource is allowed to deteriorate or disappear. Sheep in a mountain pasture are a renewable resource only as long as the pasture produces vegetation that will nourish and support the sheep. If the pasture is overgrazed, the vegetation destroyed, and the soil eroded, sheep cease to be a renewable resource in that locality.

Species renewability. The renewability of a living resource varies with the species and with the areas involved. Thus, annual plants, from which a high percentage of cultivated field crops are derived, grow to maturity each year and then die back. They are annually renewable and can be cropped at a relatively high rate. Perennial plants, such as fast-growing poplar trees, may have a much slower rate of renewability, although this depends upon the purposes for which they are used. If seedlings are in demand, they can be cropped annually, and a new supply can be grown from protected seed sources. More realistically, however, the cycling time for these trees depends on the length of time required for them to grow to maturity and to produce seeds from which a new crop can be grown. Certain conifers, such as the Monterey pine, can reach a size adequate to yield useful timber and other wood products in less than 30 years. Other conifers, desirable because of the quality of their mature wood, may be cropped only on a 100-year cycle. Old-growth redwood trees can almost be considered a nonrenewable resource, because the time required to produce their equivalent may be from 500 to several thousand years, well beyond the limits for which people are prepared to plan. Redwood forests used for timber production are managed on the basis of a much shorter cycle and the cutting of younger trees. Such management does not provide for the replacement of 1,000-year-old specimens.

Renewability of annual and perennial plants

Landscape renewability. A distinction should also be made between renewable species and the communities or landscapes they occupy. Although it takes about 100 years to replace a mature coniferous tree, certain types of coniferous forests that are managed for timber production can be logged almost indefinitely if the annual level maintains a sustained yield. When all the interrelationships among such factors as soils and plant and animal life are considered, a natural forest that has not previously been disturbed by people may be far less renewable in its totality than the individual species within it. In other words, although the procedures employed in the harvesting of timber may assure a sustained yield, they may, nevertheless, be disruptive to other forms of life in the forest community, in which case species that are intolerant of such disturbance may disappear. It may be exceedingly difficult, therefore, to regrow a new community that resembles the original primitive forest if the area is to be disturbed periodically by timber cutting. It was this consideration, among others, that engendered the need to protect national parks, wilderness areas, and undisturbed research reserves. From certain viewpoints a wilderness is a nonrenewable resource; if it is seriously disrupted by human activity, it could require hundreds of years to recover its appearance and the various natural combinations of plant and animal life that contributed to its original wilderness value. The redwood-forest wilderness, as previously noted, could require many thousands of years for complete recovery following a major disturbance. Certain tropical rain forests that were disturbed more than 400 years ago still have not regained their original balance of species and do not resemble undisturbed, primary rain forest in the same region.

Ecosystems. Resources that contain a combination of interacting living and nonliving components are called ecosystems. It is impossible to separate an ecosystem into its living and nonliving components, because the whole constitutes a dynamic system in which there is a flow of energy from sunlight, gases from the atmosphere, and minerals and water from the soil. As a natural resource, soil, in turn, is also a combination of living and nonliving components: it consists of atmospheric gases, water, living and dead organic materials, and more or less finely divided mineral substances. Moreover, soil is a product of the interaction between the living and the nonliving environment. The living components of soil fit the definition of renewable resources, within the limitations that have been noted, and the mineral components fit the definition of nonrenewable resources. As long as the living components of soil remain healthy and continue to function, the mineral components are recycled from the soil, through the organic life within it (*e.g.,* bacteria and other microorganisms), and back to the soil following the decay and breakdown of dead organic materials. Because most forms of terrestrial life are dependent upon it for their continued existence, soil must be maintained in a renewable state. Mining soil, or using it in such a way that its fertility is exhausted and it is washed or blown away by too-rapid erosion, reduces the likelihood that life can continue to exist in the area affected.

Ecosystems defined as resources

Solar energy. The supply of solar energy represents an inexhaustible resource in relation to human time scales, and it is not affected by human activities. The potential lifetime of the Sun is in hundreds of millions of years, barring cosmic accidents, and throughout its lifetime the amount of energy reaching the Earth from the Sun could be capable of meeting all human needs. That energy supply, however, depends on the condition of the atmosphere, which can be affected by human activities. For example, scientists warn that even a limited nuclear war would darken the sky with smoke and other particulate matter, causing a marked drop in surface temperatures known as nuclear winter.

Solar energy can be captured directly, as in the space heating of buildings, the heating of fluids in solar collectors, or the conversion of that energy to electricity using photovoltaic cells. It can also be captured indirectly by powering the hydrologic cycle, thereby making solar energy available as water power, or by photosynthesis, thereby converting solar energy stored in plant tissues. Plants, in turn, contribute biomass, which can be converted to alcohol fuels or burned directly to provide heat. In the 1980s,

for example, wood fuel provided more of the energy used in the United States than did nuclear power. In developing countries, wood is often the major supplier of energy. In whatever form it is used, solar energy can be expected to play a growing role in meeting human energy needs.

Water. Water may also be considered an inexhaustible resource because the total supply of water in the biosphere is not affected by human activities. Water is not destroyed by human uses, although it may be held for a time in combination with other chemicals. To be useful, however, water must be in a particular place and of a certain quality, and so it must be regarded as a renewable, and often scarce, resource, with recycling times that depend on its location and use.

Hydrologic cycle as an annual renewable cycle

Water that falls from the atmosphere as various types of precipitation and then runs off the land surface to form streams and rivers that eventually reach the ocean generally operates on a one-year-renewable cycle known as the hydrologic cycle. From the ocean the water is evaporated by solar energy and returned to the atmosphere, from which it again falls as rain or some other form of precipitation. In certain locations, however, water has a much longer cycling time; after entering the ground from rainfall, it may percolate slowly through underground channels until it reaches underground reservoirs. In certain arid regions the total water supply may be underground water that accumulated during past ages, when the climate of the region was more humid. Since that time there may have been little or no addition to this supply because of the existing climatic conditions. Because its cycling time may be extremely long and dependent upon the frequency with which wet and dry climates alternate in a particular region, such a water resource can be virtually nonrenewable.

Air. Air is also an inexhaustible resource in the sense that the uses made of it have little effect on its total quantity. The quality of air, however, as measured by its chemical composition or physical state, is subject to human interference. For life to exist on Earth there must be a proper balance among the nitrogen, oxygen, carbon dioxide, water vapour, and other components of the atmosphere. A layer of the gas ozone, for example, must be maintained in the upper atmosphere to screen out damaging ultraviolet light from the Sun. The accumulation of toxic materials in the air must be kept to a minimum, and the concentration of solid and liquid particles in the atmosphere must not be allowed to reach a level that interferes with the flux of solar radiation. All of these factors are affected by human activity and by the effects of this activity on other forms of life.

NONRENEWABLE RESOURCES

As noted above, renewable resources include resources with widely different cycling times, some so long as to make the resources essentially nonrenewable. Fossil and nuclear fuels and minerals also exhibit a wide range of properties that affect their management. Fossil fuels, such as coal and petroleum, are the least renewable of such resources because they are effectively exhausted by use and because their rate of formation is exceedingly slow. Most minerals, on the other hand, are not destroyed by use; thus, in a sense, they are renewable and inexhaustible because they can be recycled for further use. But useful supplies of these minerals in accessible locations are exhaustible, and thus they are nonrenewable for human purposes.

Fossil fuels. Fossil fuels are those organic materials that have been converted from their original form by physical and chemical processes within the Earth's crust into a solid mineral state (coal), a liquid (petroleum), or a gas (natural gas). If these substances are completely burned (oxidized) when used as fuel, the end products are carbon dioxide, water, and heat energy. These cannot be reconstituted into organic substances without either elaborate synthesis in a chemical laboratory or the natural photosynthetic processes of green plants. Thus, burning destroys fossil fuels as useful energy sources. Fossil fuels are also used for purposes other than fuel. Coal and petroleum are used industrially for the manufacture of a wide variety of carbon-containing materials, such as plastics, synthetic fibres, medicines, and food.

On the basis of existing knowledge of the amount of fossil fuels in the Earth's crust, it has been predicted that the availability of petroleum and natural gas could be greatly depleted within a century if used at the rates anticipated. Although coal supplies are greater, projected rates of use indicate that they cannot be expected to be easily available for more than a few centuries. These predictions can be changed, of course, if rates of use change, which is expected to happen with, for instance, the further development of renewable energy resources.

Nuclear fuels. Although nuclear fuels are inorganic substances, like fossil fuels they are destroyed when they are used in the production of heat energy. Unlike fossil fuels, however, they are also destroyed by spontaneous disintegration, through natural radioactivity. Uranium, for example, ultimately changes to lead, but the rate of change is very slow; its half-life (the length of time it takes for half the atoms of a given amount of a radioactive substance to disintegrate) is 7,600,000,000 years. Of the naturally occurring nuclear fuels, uranium and thorium, only uranium-235 can be used directly in a nuclear reactor for the production of power. The more common form of uranium, uranium-238, must be converted into plutonium before it can be used as a nuclear fuel. Similarly, thorium must be transformed into uranium-233 before it is usable for fuel purposes.

Uranium and thorium

Although supplies of uranium and thorium are relatively abundant, they are exhaustible and nonrenewable. By replacing nuclear fission with nuclear fusion as a power source, however, deuterium (an isotope of hydrogen) can be used as the fuel. Because it occurs in substantial quantities in seawater, deuterium is practically an inexhaustible resource for human purposes. However, many technological difficulties remain to be overcome before nuclear fusion can be used as a commercial supply of energy.

Minerals. Certain minerals, such as iron and aluminum, are so widely distributed throughout the crust of the Earth that the amounts exceed any foreseeable human needs. Other minerals, such as the precious metals (*e.g.*, gold, platinum, silver), are much more limited in their distribution and quantity. The usefulness of a mineral, however, depends upon its accessibility and concentration; therefore, minerals that are highly dispersed throughout the Earth are essentially unavailable, even though their total quantity may be great.

Ores and reserves. Most efforts to obtain minerals are directed toward finding mineral ores, which are deposits in which the concentration and quantity of a mineral are such that it can be extracted profitably. Mineral reserves are those that are known to exist or can reasonably be inferred to exist from geologic evidence. It follows that certain deposits of minerals that are not now considered either ores or reserves may become so if the technology for their extraction improves, if the supplies of energy available for their extraction increases, or if their economic value increases.

It is known from past experience that ore deposits can be exhausted. Because the gold mines around Virginia City, Nev., and the tin mines of Cornwall no longer can produce significant quantities of minerals, they can be considered virtually exhausted resources. The rich iron ores of the Mesabi Range in Minnesota have largely been depleted, and mining activity in this area has shifted to lower grade iron-ore deposits. The supplies available from any mineral deposit, at least on dry land, are exhaustible and nonrenewable because the geologic processes that led to the formation of those deposits operate slowly and over long periods of time.

Some mineral deposits, however, are renewable. Manganese ore, for example, is relatively scarce on dry land but is continuously formed in nodules on the ocean floor, as are cobalt, nickel, and copper. The rate at which the nodules of manganese, cobalt, and nickel are growing through chemical precipitation from seawater currently exceeds the rate at which these minerals are being used. Although the nodules are not yet being collected, the technology for doing so is being developed. Then these metals will be considered as renewable natural resources only so long as the rate of use does not exceed the rate of formation.

Oceanic mineral deposits

Recycling of minerals. The use of most metals does not destroy them, although rusting may reduce their quantities by a small amount when they are in use. As commercial products, some metals are found in such large quantities in urban areas that their new concentration may exceed that which existed while they were in the ground. Cities, therefore, may be considered as ore deposits for certain minerals. At present it is cheaper to mine new ores than to recycle used or waste metals (with some exceptions, such as aluminum), but this economic balance does not take into account the cost of disposing of the metallic wastes that accumulate in urban regions. Thus, it is likely that sometime in the future many metals now considered as exhaustible, nonrenewable resources will be treated as recyclable resources.

Not all minerals can be recycled under existing conditions. The concentrated phosphates that are used in fertilizers and detergents, for example, are dispersed widely over the farmlands and waters of the Earth, from which they enter the life cycles of various organisms and eventually, through erosion or in wastes, reach the oceans. Because these phosphates are virtually irretrievable and because the rate at which available reserves are being used probably exceeds the rates at which new reserves are formed, such minerals are considered as nonrenewable and exhaustible resources.

Management of natural resources

MANAGING NONLIVING RESOURCES

Soils. *Formation of soil.* Soils are the basis of support for most terrestrial life and a source of nutrients for freshwater and marine life. As noted above, soil is formed over time as the result of interaction between the living and the nonliving environment—climate, organisms, and the physical surface of the Earth. Rocks are broken apart by the action of sunlight, wind, rain, snow, sleet, and ice. With the aid of wind and water movements as well as gravity, rock particles from high elevations are deposited on mountain slopes or in valleys, where they are further acted upon by the local climate, by plant and animal life, and by such other environmental factors as fire until they become soil. Nitrogen from the atmosphere, formed into nitrates by the action of lightning and atmospheric water vapour, may enter the soil with rainfall. Other nitrates may be added by the action of such living organisms as soil bacteria and various algae that can convert atmospheric nitrogen into the nitrates required for plant growth. These and other chemicals in the soil eventually become part of the living tissue in plants and animals. The chemicals are returned to the soil as organic wastes and litter that form humus, which is partly decomposed organic material. As humus continues to decompose, the chemicals within it enter the soil for further use by plants and animals.

Soils vary from place to place depending upon the rocks and minerals from which they are derived, the nature of the local climate, and the kinds of organisms that live in or on them, as well as the amount of time that these factors have been operating. Developmental soils—*i.e.,* those still being modified by climate and organisms—reveal the nature of the parent materials from which they are derived; mature soils, those that have achieved a balance among the various forces operating on them, show in particular the influence of the climate and vegetation in which they develop. Soils also differ greatly in their inherent fertility and in their ability to support life. Those derived from quartz sand, for example, may be naturally deficient in calcium, magnesium, and other elements essential to plant growth. The surface layers of those soils developed in humid, forested regions are often heavily leached, as rainwater containing weak organic acids percolates through them and dissolves the more soluble minerals.

Developmental and mature soils

Because soils are essential for such purposes as growing crops, forage, and timber, it is important that they not be allowed to wash or blow away more rapidly than they can be regenerated, that their mineral fertility not be exhausted, and that their physical structure remain suited to the continued production of desired plant materials. The objective of soil management, therefore, is to keep soil in place and in a state favourable to its highest possible productive capacity.

Soil erosion. In the past and, to a considerable degree even now, soils have not been managed effectively. Those exposed through cultivation to the erosive effects of wind have been blown away; those laid bare on sloping ground have been washed downhill by rainfall. Although soil erosion has long been recognized as a major conservation problem, erosion as such—and its converse, the deposition of eroded soil particles—is not a problem but a normal and natural process leading to both soil development and maintenance. Soils exist only because of past erosion and deposition. The conservation problem involved in soil erosion is the accelerated erosion that occurs when soil cover in the form of living or dead plant material is removed. In such cases the soil then erodes at a rate faster than it can be replaced by normal deposition of particles on the soil surface or by the breakdown of rocks and minerals. In severe cases, such erosion leads to the formation of deep gullies that cut into the soil and then spread and grow until all the soil is removed from the sloping ground. Under severe wind action, the finer particles of surface soil are blown away and form drifts and dunes, leaving only the coarser sands and gravels on the soil surface.

Erosion of organic soil cover

Although measures to stop soil erosion are now used in most technologically advanced countries, the problem remains a major one. It is particularly severe in the tropics, where high rainfall and steeply sloping ground favour the rapid loss of any soil exposed by agriculture, and around the edges of the world's deserts, where destruction of natural plant cover by cultivation or livestock grazing causes soil loss through wind action and the spread of desert-like conditions.

To prevent wind erosion, shelter belts of trees have been planted to break the force of the wind. The practice of covering soils with plant litter (mulch) when they are not actually covered with growing plants also helps to hold them in place. Cultivating at right angles to the direction of the wind further serves to prevent wind erosion.

Water erosion on sloping ground may be prevented by terracing on steep slopes or by contour cultivation on gentler slopes. In the latter a slope is plowed along horizontal lines of equal elevation. Strip-cropping, in which a close-growing crop is alternated with one that leaves a considerable amount of exposed ground, is another technique for reducing water erosion; the soil washed from the bare areas is held by the closer growing vegetation. In the tropics maintaining a tree shelter over the ground serves as a means for breaking the force of raindrops, thus reducing their erosive power, and also to screen out direct sunlight. In addition to causing damage to certain crops, sunlight can accelerate the breakdown of organic materials in the soil at a rate that is faster than is desirable.

Soil fertility. A conservation problem equally as important as that of soil erosion is the loss of soil fertility.

Figure 2: *Soil erosion and ways to prevent it.*

Most agriculture was originally supported by the natural fertility of the soil; and, in areas in which soils were deep and rich in minerals, farming could be carried on for many years without the return of any nutrients to the soil other than those supplied through the natural breakdown of plant and animal wastes. In river basins, such as that of the Nile, annual flooding deposited a rich layer of silt over the soil, thus restoring its fertility. In areas of active volcanism, such as Hawaii, soil fertility has been renewed by the periodic deposition of volcanic ash. In other areas, however, natural fertility has been quickly exhausted. This is true of most forest soils, particularly those in the humid tropics. Because continued cropping in such areas caused a rapid decline in fertility and therefore in crop yields, fertility could be restored only by abandoning the areas and allowing the natural forest vegetation to return. Over a period of time the soil surface would be rejuvenated by parent materials, new circulation channels would form deep in the soil, and the deposition of forest debris would restore minerals to the topsoil. Primitive agriculture in such forests was of a shifting nature: areas were cleared of trees and the woody material burned to add ash to the soil; after a few years of farming, the plots would be abandoned and new sites cleared. As long as populations were sparse in relation to the area of forest land, such agricultural methods did little harm. They could not, however, support dense populations or produce large quantities of surplus foods.

Starting with the most easily depleted soils, which were also the easiest to farm, the practice of using various fertilizers was developed. The earliest fertilizers were manures, but later larger yields were obtained by adding balanced combinations of those nutrients (*e.g.,* potassium, nitrogen, phosphorus, and calcium) that crop plants require in greatest quantity. Because high yields are essential, most modern agriculture depends upon the continued addition of chemical fertilizers to the soil. Usually these substances are added in mineral form, but nitrogen is often added as urea, an organic compound.

Fertilizers and crop rotation

Early in agricultural history it was found that growing the same crop year after year in a particular plot of ground not only caused undesirable changes in the physical structure of the soil but also drained the soil of its nutrients. The practice of crop rotation was discovered to be a useful way to maintain the condition of the soil and also to prevent the buildup of those insects and other pests that are attracted to a particular kind of crop. In rotation systems a grain crop is often grown the first year, followed by a leafy-vegetable crop in the second year and a pasture crop in the third. The last usually contains legumes, because such plants can restore nitrogen to the soil through the action of bacteria that live in nodules on their roots.

Salinization of soil. In irrigation agriculture, in which water is brought in to supply the needs of crops in an area with insufficient rainfall, a particular soil-management problem that develops is the salinization (concentration of salts) of the surface soil. This most commonly results from inadequate drainage of the irrigated land; because the water cannot flow freely, it evaporates, and the salts dissolved in the water are left on the surface of the soil. Even though the water does not contain a large concentration of dissolved salts, the accumulation over the years can be significant enough to make the soil unsuitable for crop production. Effective drainage solves the problem; in many cases, drainage canals must be constructed and drainage tiles must be laid beneath the surface of the soil. Drainage also requires the availability of an excess of water to flush the salts from the surface soil. In certain heavy soils with poor drainage, this problem can be quite severe; for example, large areas of formerly irrigated land in the Indus basin, in the Tigris–Euphrates region, in the Nile Basin, and in the western United States have been seriously damaged by salinization.

Watershed soil. The soils of wildlands in all areas that yield water to streams and rivers are as important as are those in which agricultural crops are raised. If these soils are kept in place and in good condition, they support trees, forage, and wild animal life and yield clear water for human use. If, however, these soils are damaged physically by being compacted or are allowed to erode, they lose not only their capacity to support vegetation but also their capacity to hold and slowly yield useful water to streams or springs. Furthermore, eroded soils cause siltation of waterways; they also accumulate in lakes and reservoirs, filling them and thereby reducing the useful purposes that these bodies of water serve.

In order to maintain soils in watershed areas, their vegetative cover must be retained. This requires avoiding excessive disturbance of forest vegetation and soil cover through logging, avoiding excessive grazing and trampling of pasture lands, and preventing the kinds of wildland fires that destroy plant cover and expose the soil. Often, the success of intensive land and water use downstream depends on the care taken of the soils in the less intensively used forest or range watersheds upstream.

Water. Life originated in the oceans, and the chemical composition of body fluids in land animals reflects their primeval origin. The dependence of life on water is complete; it is the major constituent of plant and animal cells. Most of the major groups of animals still live in water; a relatively small number have adapted to life on dry land.

Dependence of life on water

Uses of water. Water is required for a variety of purposes; water for drinking is still paramount, and such water must be relatively pure. If it is not supplied in sufficient amounts through precipitation, it must be supplemented by irrigation systems. Irrigation, however, is one of the most wasteful uses of water in areas in which it is scarce, because great quantities are lost through evaporation in both storage areas and transport. In many regions irrigation is, nevertheless, essential for human survival.

Water for transportation has always been important, as indicated by the fact that most major cities are located on the shores of oceans and other large bodies of water or along rivers and other types of navigable waterways. Despite recent advances in ground and air transportation, water transportation has an economic advantage for the movement of goods that have a relatively low value per unit of weight or volume, such as raw mineral ores, fuels, and various types of construction materials. Water for urban use other than drinking serves a multitude of purposes, such as fire fighting, street cleaning, sanitation, and sewage disposal. Steel mills, pulp mills, chemical factories, and most other industrial processes that involve the conversion of raw materials into finished products require water. Next to agriculture, one of the most extravagant uses of water is as a cooling fluid in the generation of power from fossil and nuclear fuels, with the latter consuming far greater volumes. Water has been used directly as a source of power since the time of the first boat and the first waterwheel. A small but important part of the world's electrical supply now is generated by hydropower, in which the force of falling water is used to turn turbines that produce electricity.

Husbandry of water supplies. Although water is a renewable resource, the many demands for water of a desired quantity and quality in a particular place require careful husbandry of the supply. After reaching the surface of the Earth as rain, water enters a supply system either by penetrating the ground and moving through subsurface channels, known as aquifers, or through runoff into streams and rivers. As mentioned above, the supply and quality of water depend in part on the management of the vegetation and soil in the watershed areas. Also involved is the control of streamflow or the control of pumping from underground sources. In many parts of the world where rainfall is seasonal, streams run at flood levels during the wet season but are extremely low or completely dry at other times of the year. River-basin-management techniques attempt to equalize this variable supply for human purposes, in part through watershed management and in part through the capture of water by dams and its storage in reservoirs.

Consequences of mismanagement of water

When water is mismanaged, a high percentage is lost through evaporation in watersheds. Moreover, as a result of poor management of watersheds, the seasonality of water flow is more acute: floods that destroy lands in the river basins become more frequent during the wet season, and there is an increase in the frequency of droughts during the dry or low-rainfall season. Soil eroded from watersheds impairs the functioning of dams, reservoirs, and other structures downstream. Furthermore, because of mismanagement water becomes polluted at various stages in its movement from atmosphere to land and thence to the oceans.

Effective water management starts when precipitation first reaches the ground, after which the quality and quantity of water must be protected at every critical point along the hydrologic cycle. Hence, although it may have been practical to use streams, lakes, and the oceans as dumping areas when populations were low and water was abundant, this practice becomes untenable when populations increase and supplies of water decrease relative to human needs. Except in sparsely populated areas of the world, population and technological growth have made necessary the prevention of erosion, the recycling of wastes so that nutrients are restored to the soils and useful minerals are reclaimed for reuse, and the reuse of water to the maximum possible degree. In many dry areas the wasteful use of groundwater, stored in aquifers, has caused a serious lowering of water tables and even a sinking of the land surface. Such cases call for limiting the use of water supplies to more essential and less wasteful purposes.

"New" sources of water. Lack of water of proper quality and quantity has been a major factor affecting urban and industrial growth. To overcome this problem, water has been transported great distances—*e.g.,* the channeling of Rocky Mountain water from the Colorado River to Tucson, Ariz. During the 1970s and 1980s the Soviet Union proposed several projects to reverse or divert the waters of northward-flowing rivers of Siberia and the Russian S.F.S.R. to meet the demands of the more heavily populated and water-short regions of the Volga Basin, Central Asia, and Kazakhstan. The predicted environmental and climatic consequences of such undertakings, however, combined with their engineering logistics, prevented the practical application of most of these plans.

The use of the oceans as sources of fresh water is being developed in many areas. Kuwait, a desert nation in Arabia, now receives much of its water supply through the desalinization of seawater, as do a number of small communities and several large urban centres elsewhere in the world. Seawater may be used as a source of fresh water on a more widespread basis if an additional power source—*e.g.,* solar power—can be developed for the desalinization process. Morever, the materials reclaimed from seawater could, if power is available for their separation and concentration, help in meeting many of the world's mineral needs. It seems unlikely, however, at least with foreseeable sources of power, that desalinized ocean water will be extensively pumped to inland regions. Meeting the growing needs of such areas will require the purification of waters polluted by urban or industrial use or of waters that have become salinized through their use in irrigation. The reuse of such waters could go far toward reducing the need for new water by inland communities.

Desalinization of seawater

Air. Concern about the quality of air is a relatively recent development, although polluted air has been a problem for urban communities over many centuries. The atmosphere makes possible the existence of life, and in the solar system only the planet Earth has an atmosphere capable of sustaining known forms of life. Seventy-eight percent of the Earth's atmosphere consists of nitrogen, a gas that, combined with other elements, is a key ingredient of plant and animal protein. Most essential to terrestrial life is oxygen, which makes up nearly 21 percent of the atmosphere. The remaining 1 percent includes argon (an inert gas), carbon dioxide, and water. The latter two, despite their small quantities, are vital to life. Sunlight acting on water is the driving force for the world's weather. Carbon dioxide is essential to plant growth and thus to animal life.

The supply of oxygen in the atmosphere has been relatively constant during recent centuries, but its presence is believed to depend on the activities of living organisms. Green plants, through photosynthesis, and photosynthetic microorganisms built up the present level of atmospheric oxygen and provide for its continued maintenance.

The atmosphere extends above the surface of the Earth to a distance of many thousands of miles, but 95 percent of its total mass is to be found within 12 miles of the surface. The layer of atmosphere closest to the surface (extending upward to heights of four to 11 miles) is known as the troposphere. It is only within this zone that life is supported. It is also where water vapour, and hence storms and precipitation, occurs. Above the troposphere

is the stratosphere, extending up to 31 miles above the Earth. Most important to life is the ozone layer within the stratosphere. Ozone (O_3) is a form of oxygen that blocks out the shorter wavelengths of solar radiation and thus protects life on the Earth's surface from the damaging effects of ultraviolet light.

There is not much that can be done to manage the atmosphere. What must be done, however, is to manage those activities that affect its composition (see below *The pollution of natural resources: Air pollution*).

Subsurface deposits. Several types of conservation activities are associated with the use of fossil fuels and minerals. First are those that involve making the available fuel and mineral reserves serve the most worthwhile purposes for the longest period of time. Second are the problems associated with extracting fuels and minerals from the ground and their subsequent transport, processing, and manufacture, all of which can directly affect the quantity or quality of other resources or the general environment. Third are the side effects, which, because they involve pollution, are considered below.

Conserving exhaustible fuel and mineral resources. As has already been noted, fossil fuels and minerals fall into two categories: those that are destroyed by use and those that retain their physical and chemical characteristics during use and are capable of being reclaimed for other uses. The outlook is most bleak with respect to the conservation of those fuels and minerals that are destroyed by use. If petroleum continues to be used at its present rate, the supply will be exhausted or reduced to a level at which further use may be restricted by the high cost of the remaining resource. Because the situation is generally recognized, conservation need involve only allocating the resource to those uses for which it is best suited and restricting its use in those cases in which other materials, less likely to be exhausted, can be equally well substituted. Thereafter, it is necessary to maximize the available resource. This can be done by avoiding waste in its extraction, transportation, and processing and by utilizing fully all that can be made available. Thus, several oil companies no longer pump competitively from the same oil field, leaving only unobtainable oil in the ground. Instead, fields have been unitized; companies now cooperate in bringing out oil by using only strategically located pumping units. The practice of burning the natural gas from oil fields has been replaced by tapping and piping the gas for use as a fuel. Unrestrained gushers are a thing of the past; more important are the methods of drilling and of injecting gas or water under pressure to force out oil that previously would have been left in the ground. Improved methods for refining petroleum have eliminated much of the waste that once occurred in this process. Yet accidental losses still do occur. The leaking well that caused such extensive damage to wildlife and recreational resources in the Santa Barbara, Calif., channel in 1969 resulted in part from failure to use available safety devices. Similar failures were involved in an oil well off the Louisiana coast in 1970 and in the blowout of the Ixtoc 1 oil well in the Bay of Campeche, which spilled oil on the coasts of Mexico and Texas in 1979. Great quantities of oil are still wasted and waters polluted because of improper navigation of oil tankers and because some such tankers are so poorly constructed that excessive quantities of oil can escape as a result of relatively minor damage to the hull.

Maximizing available resources

Beneficiation, the concentrating of relatively dispersed or low-grade resources into a form in which they can be handled economically, is another means of extending the supply of exhaustible petroleum resources. There are, for example, great quantities of petroleum available in oil shales and tar sands in various parts of the world. As long as petroleum is plentiful in a more concentrated form in oil fields, it is not economical to extract the more dispersed petroleum in such shales and sands. With the prospect of an eventual shortage of petroleum, however, techniques have been devised for concentrating these lower-grade supplies. The technologies of extracting oil from petroliferous sand or shale differ, but both involve the heating of the extracted oil-bearing medium. Most oil sand has been extracted by surface mining techniques; the extracted sand is then heated or coked, and the distillates are transformed into synthetic crude oil by high-pressure hydrogenation. Oil shale has been generally mined, crushed, and heated or retorted at high temperatures to produce crude oil.

Recycling

Conservation in the case of recyclable minerals involves reuse. For this to be accomplished, incentives and methods may be necessary to encourage the gathering of used materials for reprocessing. Provisions have been made for the collection of junked automobiles, waste cans, bottles, and other containers and for the reuse of building materials from demolished structures. Although much of this is done more to prevent pollution than to reclaim the materials, it does serve both purposes. Another conservation measure is waste-processing technology and the growth of industries concerned with the recycling of wastes.

Just as applicable to the conservation of minerals as they are to the conservation of petroleum are such other techniques as the allocation of scarce resources to their most essential uses, the substitution of other resources for those that have become scarce, and the maximization of supplies. Moreover, there has been great progress toward the development of composite materials, in which relatively small amounts of metal are used in combination with plastics and ceramics. Metallic alloys that minimize the need for scarce materials (as in the substitution of various cheaper metallic alloys for copper or silver in coins and the substitution of aluminum alloys for copper or steel wire, for roofing materials, or for tin in cans) are in many cases more effective than those used for the same purposes. Beneficiation has been used increasingly; thus, low-grade taconite and jasperite ores are now being mined and pulverized, and their iron components separated and pelleted before being shipped to smelters. Such techniques make possible the use of iron deposits that previously would not have been considered economical sources of ores.

Predictions of depletion of a resource

Because of the many ways for making better use and reuse of the available supply of metals and other minerals and because the extent of new discoveries cannot be foretold, it is difficult to predict the likelihood of depleting any particular mineral resource; for example, the wasteful use of metals and minerals in most affluent societies creates a drain upon supplies that is entirely unnecessary. Predictions of resource use based on the continuation of wasteful practices are likely to prove unrealistic if these practices are changed voluntarily or forced to change by a scarcity of materials.

Conservation problems caused by mining. Some of the most serious conservation problems are associated not with the use of minerals or fuels but with the methods used to extract these resources. Mining for coal has created widespread devastation in the Appalachian Mountains of the United States, in Bohemia (Czech Republic), and, in the past, in England and Germany because deposits in these regions were found near the surface. In the removal of the coal, soil and living resources were destroyed, leaving behind a barren, denuded, and eroded wasteland. Because mining wastes often contain much sulfur, their watery runoff contains sulfuric acid, which destroys aquatic life in streams. Similar problems are associated with the surface mining of nickel in such places as New Caledonia and Australia. Dredging for tin in Malaysia has also created widespread conservation problems. The mining of phosphates has brought destruction to many Pacific islands, in particular to the island of Nauru. Titanium mining in the sands along the Australian coast has destroyed natural vegetation on beaches, sand islands, and dunes and opened pathways for dune movement that destroys still greater areas of vegetation. Dredging for gold has damaged many streambeds and riverbeds because it is destructive to aquatic life and water quality.

The means for preventing damage by surface mining do not exist, but damage can be controlled and minimized, in part by the creation of erosion-control structures and the prevention of water pollution. The rehabilitation of mined-over land may involve, among other things, the removal and safe storage of topsoil before mining begins and its restoration after mining operations have been completed. It may also involve the shaping of mining wastes into

landforms that can be covered with soil, replanted, and revegetated. Of equal importance, however, is the decision not to mine areas that have high surface-resource values—*e.g.*, highly productive forest or farmlands, certain urban areas, and areas with natural qualities of scenery, plant life, or wildlife that make them suitable to be maintained as parks or reserves. The ores in such areas are not mined unless the need for their minerals is most urgent.

MANAGING LIVING RESOURCES

Any area of land and water not yet modified by mankind can be managed in a number of ways. Certain choices must be exercised early, however, because even minor deterioration of an area through unplanned use may make it unusable for its intended purposes. Other choices, particularly those involving modification of the natural features of the landscape, may be exercised at virtually any time; any previous changes in the character of the living resources in a region to be modified have no effect on the ultimate structural modification of that region. In planning for the use of any undeveloped area, therefore, those purposes that have the most exacting requirements must be considered first; they often depend upon the continuance of relatively undisturbed conditions as well as upon the maintenance of the full variety of wild species and the natural environment within the area.

Natural communities. The idea that biologic communities should be protected for their own intrinsic value is of relatively recent origin. Although natural communities have been protected since ancient times, the reasons for doing so have not been related to the value of the community per se but to some special feature that was of value to people. Thus, hunting preserves were protected in ancient Mesopotamia, in China, and in England, where the New Forest was set aside by William the Conqueror. While such preserves protected natural areas, their major purpose was to provide a setting for royal hunting. Temple gardens have been preserved over the centuries in China and Japan; the cedars of Lebanon were maintained around holy places. But, again, such preservation was fortuitous rather than intentional.

The idea of preserving wild areas for their own value had its origin in the United States with Catlin, Thoreau, Muir, and others of similar mind. Only more slowly has this concept been accepted in other countries. Appreciation of wild nature is acquired along with scientific knowledge, particularly ecological knowledge. It is a sophisticated taste not usually to be found among those who earn their livelihood in close contact with the wild. Nevertheless, the concept of preserving wild nature for its own value has become widely accepted, although the means for implementing it are not necessarily available in every country.

Value of natural communities

Natural communities, little affected by human activities, are thought to be worth preserving for a variety of reasons. First, perhaps, is the scientific benefit to be derived from studying them, particularly concerning the functioning of the biosphere. From studies of undisturbed ecosystems much can be learned about the behaviour of those systems modified for the production of useful materials. Also, the value of wild species has been little explored; in their totality they are known to be essential to the function of the biosphere, but the importance of individual species is little understood.

Past experience has demonstrated that wild species of little apparent value may prove to be of major importance to medical research and human health. Sea urchins, for example, are used in studies of embryology; nonhuman primates (*e.g.*, monkeys and apes) are used for many studies of human functions and diseases; armadillos are used to study leprosy; and a great variety of wild plants are used as sources of drugs and medicines. Much of the knowledge of population growth and social behaviour under various conditions of crowding has come from the study of wild mammals.

Furthermore, it is known that more or less undisturbed natural communities are important to the continued operation of those systems that people have created. Watershed forests are protected so as to maintain streamflow and to avoid siltation of reservoirs; estuaries are protected so as to guarantee the continued production of forms of marine life important for food or other purposes. Finally, there are aesthetic and recreational values attached to wild areas and wildlife. It would appear that outdoor activities in a natural setting or contact with plants and animals in a wild state are important to psychological well-being, because people of all races and cultures seek such experiences when they achieve the affluence that enables them to do so.

Protection of natural communities

Biologic communities can be protected in a variety of ways, depending upon the desired objectives. The most difficult and exacting task is the protection of unmodified natural communities, with their full array of wild species, for use in scientific research. Because such communities are becoming increasingly rare, the major efforts to protect them are undertaken at an international level, as well as at the national level. The International Biological Program, a worldwide research effort, has focused attention on the many kinds of natural communities that require protection. The International Union for Conservation of Nature and Natural Resources, a semigovernmental international agency, devotes an important part of its activities to the establishment of reserves and parks for the protection of natural communities. The United Nations, through its Food and Agricultural Organization (FAO), UNEP, and UNESCO, has contributed to the establishment of many parks and reserves in developing nations. Yet, despite such activities, certain kinds of natural communities will be irrevocably lost unless there is greater effort toward their conservation.

The danger to natural communities and wild species comes from many causes. One long-standing problem derives from the exploitation of wild species that have commercial value, as, for example, the widespread removal of

mahogany trees and other valuable timber from the forests around the Caribbean area. The uncontrolled hunting of whales and other sea mammals has brought some species to the point of near-extinction, and at least one, Steller's sea cow, has been exterminated. The demand for such high-fashion products as shoes and handbags made from crocodile skins or coats and wraps made from the skins of tigers and leopards has endangered the continuing existence of these animals.

Control of those species considered to be detrimental has led to an unreasonable warfare against predatory animals. As a result, the wolf, cougar, lion, lynx, eagles and hawks of various species, and other carnivorous animals have been eliminated from the vicinity of human settlements or from pastoral lands, even though the evidence that some of these species do any appreciable damage is not well substantiated. But the greatest single cause for the depletion of natural communities and wild species has been the desire to use land for more productive purposes. This has led to extensive clearing of forests and woodlands, burning of vegetation, and the cultivation of previously undisturbed land for crop production. Many of the lands that are cleared eventually prove to be poorly suited for the purposes for which they are intended and are ultimately abandoned; however, it is then no longer possible to protect the natural communities that previously existed in these areas.

Programs for the protection of natural communities must involve, first, rational planning for the use of land and control over its exploitation by agencies charged with such responsibilities. Adaptation of land use for commodity production by using only those sites best suited for such purposes is a first step toward protecting other lands that are now being cleared unwisely. Although the establishment and proper management of parks and reserves permits the survival of certain species in certain areas, a more general program of rational management and use of all lands and species is essential to the long-term survival of wild nature throughout the world.

Strict nature reserves. The decision to maintain an area in a more or less unmodified condition usually is determined by its overall scientific and aesthetic value. It may also be determined by the contributions the protected area can make to the region as a whole, as, for example, the regulation of water yield and streamflow or perhaps as a reservoir of wild species that subsequently can move or be moved into other modified regions. The most restrictive category of land use is that of the scientific reserve, which is also known as a strict nature reserve. Such areas may be selected because of their unique geologic or biologic features. Or they may be selected because they are representative of widespread biologic communities that will be transformed elsewhere for the needs of commodity production, recreational use, or other more intensive purposes. Retaining representative areas in an unmodified condition provides standards by which the health and productivity of the modified sites can be tested.

Strict nature reserves and other types of scientific reserves often occupy only a relatively small area of land. The amount of land occupied, however, depends to a large extent on the biologic requirements of the species to be protected and the interactions of the area with the surrounding region. Thus, in the rolling taiga country (swampy coniferous forests) of northern Europe, Asia, and North America, the decision to maintain a bog in a natural state may involve the protection of only a small area—the bog and those immediately adjacent slopes that drain into it. On the other hand, the decision to protect the natural habitat and population of migratory caribou in the same region could involve an area several hundred miles in length and more than 100 miles in width—a sizeable area that might include taiga and tundra. The decision to protect the natural habitat of a species of migratory waterfowl would be even more far-reaching. In addition to protecting the tundra breeding ground of such birds, protection of their resting and wintering grounds, which could lie in a different hemisphere, might also be involved. It is always easier to protect rooted plants than mobile animals. And the more mobile the species, the more difficult the task; for many migratory species, international action is required.

Difficulty in protecting migratory species

Any decision to protect an area in an undisturbed condition, however, must take ecological reality into account. The experience of Everglades National Park in the United States, which protects only the lower end of an extensive watershed, is illustrative. The stormy history of this park has involved efforts to control water and land use in areas outside the park because its future existence depends upon the flow and quality of water from those areas. By contrast, high mountain reserves, such as those surrounding Mount Kinabalu, on the island of Borneo; Mount Kenya, in East Africa; or Glacier National Park, in Montana, offer no such difficulties.

The designation of an area as a strict nature reserve is often proclaimed by law and recognized only by the appropriate governmental authorities, with no cognizance of the action by others. Such areas must have boundaries that are clearly demarcated and identifiable to prevent accidental intrusion and modification.

Because a strict nature reserve is set aside for scientific purposes, its use for recreation or any other purpose may disturb its natural integrity. Even scientific use itself can be a disturbing factor; hence, the use of such reserves is regulated by scientists. Usually a scientific advisory committee must rule on the appropriateness of any proposed research to the long-term future of the area.

The decision to protect a natural area for scientific purposes is not a simple one. In the case of most of the less affluent countries, in which neither money nor technical expertise is available, it is virtually impossible to proclaim a strict reserve and have it maintained as such except in the remotest areas. Usually international assistance is required, in money or manpower, if such reserves are to be established.

National parks. The establishment of national parks in the United States represented one of the first national efforts to protect wild nature. Yet, in establishing Yellowstone National Park, Congress made clear that it was viewed as "a pleasuring ground" for people and not as an area intended only to safeguard communities of plants and animals. It was not until the formation of the U.S. National Park Service in 1916 that the concept of managing parks so as to maintain their natural qualities was accepted. Nevertheless, the practice of killing predatory animals as "undesirable" elements of wild nature continued in U.S. national parks into the 1930s and lasted in some African national parks as late as the 1960s.

Unlike a strict nature reserve, a national park may be made available for various purposes but usually only for those forms of recreational use that do not create great changes in or require significant modifications of the natural environment. National parks usually are selected on the basis of their unique qualities, outstanding natural beauty, unusual geologic formations, or remarkable array of wild animal or plant life. They may also be selected, however, to protect areas of anthropological, archaeological, or historical importance along with the natural or artificially modified landscapes that surround them. In the United States, national parks are dedicated solely to recreational activity. National parks in England may protect cultural as well as natural landscapes, in that some may be dedicated to the preservation of traditional forms of land use that are disappearing elsewhere. Some national parks, such as in Peru, protect ethnic groups along with their hunting and gathering grounds.

Thus, exactly what constitutes a national park varies according to the nations and people involved. The dedication of an area as a national park is everywhere a highly restrictive form of land use, in which all incompatible activities are prohibited. Hunting, logging, mining, commercial fishing, agriculture, and livestock grazing are excluded from most such parks, as are urban and industrial uses not directly related to recreation. There is much debate as to whether tourist facilities should be within or outside national parks; because of their disruptive effects, the trend is to locate such facilities outside.

Facilities needed in national parks

National parks, at a minimum, require equally extensive boundary demarcation and perhaps policing and pa-

trolling as are necessary for strict nature reserves. They also require the careful planning of trails, roads, and other means of human access in order to channel the activities of visitors in ways that will not disrupt the resources or landscapes. Not only must certain fragile areas be set aside and protected from visitors, but visitor use must be concentrated in those places in which human activities will do a minimum of harm. The trend has been to divide national parks into zones that range from areas of intensive public use at one extreme to the remotest wilderness or strict nature reserves at the other.

Usually a considerable amount of money and energy must be invested in the planning and management of a national park. This is often beyond the resources of the less affluent countries unless international assistance can be provided. Because of their attraction as sites for outdoor recreation and their appeal to tourists, however, national parks often more than pay for themselves in a short period of time. In East Africa, for example, national parks are a major source of foreign exchange of the countries in which they are located because of their unique wild animal life. As a result of the body of expertise that has developed in the planning and management of national parks and because of their growing economic importance, expert direction in the establishment and maintenance of national parks is now available throughout the world whenever it is requested. Within the United Nations such assistance is offered to developing countries by UNESCO, UNEP, and FAO; outside the United Nations, assistance is available from the International Union for Conservation of Nature and Natural Resources and from the World Wildlife Fund.

Refuges and sanctuaries. A less restrictive use of an area of wildland is that directed toward the protection of certain species or groups of wild animals or plants. This type of land use includes wildlife refuges and sanctuaries as well as various kinds of botanical reservations. In such areas, use of the land that could interfere with the well-being of the protected species is excluded. Other forms of land use may be encouraged, however, if they are not in conflict or if they actually assist with the creation of a suitable environment for the protected forms of life.

Refuges and sanctuaries often are established for the preservation of endangered species of wildlife or plants, particularly those whose numbers and distribution have been seriously curtailed; examples include the Umfolozi Game Reserve, in South Africa, in which the southern species of the white rhinoceros is protected, and the Mountain Zebra National Park, in the same country. The refuges for the California condor and the Torrey pine in California are of a similar nature. Refuges and sanctuaries may also be provided for more abundant species that require protection at certain periods of their life cycle or in certain areas where they gather in order to reproduce. Many wildlife refuges and sanctuaries in the United States and Europe are of this type; they provide protected sites for the resting, breeding, or wintering of wildlife species (particularly waterfowl) that otherwise are hunted outside of the refuge. In such places management measures are necessary to enhance the habitat for the protected species and to remove any competitors or predators that might interfere with the breeding and survival of the young. Such measures would be inappropriate to parks or strict nature reserves, because their purpose is to protect a total biologic community without favouring a particular species.

Refuges as protected sites for abundant wildlife species

The various measures employed for the protection and management of living resources on land also apply to water areas. Marine and other aquatic parks and reserves have been established in many parts of the world to protect various forms of saltwater and freshwater plant and animal life. Australia, for example, has reserves that protect important areas of the Great Barrier Reef; Kenya and Tanzania have marine parks and reserves on their coasts. Lake Baikal, in the Soviet Union, is now included in a major national park designed to protect not only its unique freshwater life but also its watershed areas.

Wildlife and fisheries management. The protection of most wild animal life cannot be accomplished solely through parks and reserves. Consequently, wildlife conservation and management represent an activity that extends into other areas. As has been mentioned previously, one form of wildlife conservation with a long history of laws, regulations, and proclamations dating back to ancient centres of civilization was the protection of royal game. Wildlife conservation is also closely related to the management of fisheries, because both are directed toward the preservation of wild species and their habitats and toward increasing the productivity and yield of these species. Increased productivity in wildlife or fish may contribute to a commercial harvest, or it may make contributions to human well-being through sport hunting or fishing, wildlife viewing, or some other form of recreation.

The basis for wildlife and fishery management includes research into the ecological requirements and breeding potentials of the species involved. Protective laws and regulations are necessary to control the allowable commercial or sport take in order to guarantee that it remain within the sustained yield. Means for enforcing such laws should include the employment and deployment of adequate protective forces, preferably specially trained wildlife and fisheries wardens who are capable of identifying species likely to be killed or captured and who are familiar with the ways of hunters and fishermen. Management activities intended to maintain or improve the habitat for the wild animals concerned are also important. Special refuges of the kind already described may be essential both to control hunting and fishing pressure and to allow animals to reproduce, rest, or winter without being disturbed. In addition to these activities, wildlife conservation also involves the management of the requirements of wildlife in the areas in which the land is used for other purposes.

Commercial value of fish and wildlife

Commercial fishing, which is of great economic importance in countries with extensive inland waters or with access to the seas and oceans, contributes a significant share of world food, particularly protein. The problems of fisheries conservation are many, however. It is essential first to locate the fish and derive some estimate of their abundance. Much of the recent increase in yield by world fisheries has come from the discovery of previously little known and unexploited sources of fish. It is also necessary to determine the maximum sustained yield of the fish population. Finally, the most difficult task is the supervision and control of the fishery. Even in national waters, fisheries have been overexploited and depleted to a level such that the species concerned no longer has any commercial value—the sardine fishery of the California coast is an example. In international water it is much more difficult to regulate and control the activities of fishermen.

The commercial use of terrestrial wildlife, though not in the same economic category as fisheries, is nevertheless significant to some countries. Wild animals are killed for their meat, hides, furs, fats, oils, bones, ivory, antlers, and other by-products. Live animals are captured for zoos, for medical research, and for the pet trade. The exceedingly high prices paid for certain species, such as various primates used for medical research or those that are valued for their furs, has been of great importance in causing the reduction of some species to a dangerously low level. Despite the high commercial value of some wildlife, however, in many parts of the world their recreational or sporting value has an even greater economic importance. In the United States, for example, the commercial hunting and sale of game animals is generally prohibited, as is the commercial harvesting of certain game fish, because such wildlife is reserved for recreational use.

In technologically advanced countries it has proved practical and economically desirable to manage wildlife and fisheries so that no species becomes severely depleted. But, in those countries in which a high percentage of the people are illiterate or live near the poverty level, the protection and management of wildlife and fisheries is much more difficult to achieve. In such nations protective laws are not easy to enforce because trained wardens are not widely available and because the laws are neither understood nor accepted by the general population. Thus, the depletion of wildlife and fisheries through hunting and fishing continues in these countries, and growing numbers of species are now endangered.

Multiple-use management. A wildlife conservation area may be used for additional purposes. Throughout the world many areas of public wildland are managed on a policy of multiple use; that is, they can provide either at the same time or sequentially a variety of wildland products or services. National forests, for example, are used for recreation and to produce timber and range forage for domestic livestock, wildlife, and fish; and at the same time they stabilize watersheds and yield sustaining water supplies to natural bodies of water or to man-made reservoirs.

Conflicts in multiple use

The decision to manage an area for multiple use, however, necessitates minimization of conflicts among the various forms of use. Thus, removing the timber from an area involves the construction of logging roads, landings, and other facilities; and, while the area is being logged, most other uses are restricted. Furthermore, during and following logging, care is taken not only to provide a site and seed trees suitable for growing the next crop of trees but also to protect the natural reproduction of trees, young seedlings, and saplings. In cases involving more intensive management, seeds or seedlings are planted and given protection during the period when they are becoming established. Moreover, the value of the site for recreation or for other purposes may be greatly reduced during this process, particularly when certain systems are used for cutting timber; thus, clear-cutting, which involves the total removal of all large trees from an area, creates an appearance of greater devastation than is seen in selective cutting, in which only a few trees of a particular species and age class are removed. Obviously, clear-cutting then favours wildlife species that prefer open areas at the expense of those that require dense forest cover. Generally speaking, however, logging of timber involves the exclusive use of an area for this purpose over a period of time; other uses may not be fully restored until the vegetation or animal life has recovered from the effects of timber removal.

Development of an area for grazing by domestic livestock often includes fencing; the demarcation of livestock trails for the transfer of animals from one area to another; the provision of watering points, salt grounds, and other items essential for the welfare of the animals; and sometimes the construction of special corrals or handling chutes. When livestock are in an area, they cannot be disturbed too frequently. Livestock owners also demand the removal of any predatory animals that are likely to attack their stock. Such needs obviously restrict the development of the same site for purposes that could conflict with its use as a livestock range.

Factors involved in development for water power

Intensive development of an area for water power (*e.g.*, the construction of dams, power stations, pipelines, canals, and power lines) entails complete change of the area affected and removes much of its wild or natural quality. Although such a location is obviously less suited for wilderness or wild-country recreation, it often is enhanced for certain forms of mass recreation, such as fishing, boating, and water sports in reservoirs. Recreational development on any intensive scale also involves considerable modification of an area. The construction of tourist and visitor facilities of various kinds—trails, ski runs, campsites, roads and parking areas, lodges, and picnic grounds—necessarily restricts the use of such an area for other purposes.

The concept of multiple use thus applies mostly to the management of large areas of wildland, although within such areas various special uses may from place to place and from time to time be emphasized. Nevertheless, the governing policy of multiple use is valuable because it prohibits the exclusive use of a particular area for the benefit of any one segment of society and, instead, forces accommodation to the greatest variety of uses that best suit a particular site.

Intensive wildland uses. *Timber production.* Loss of the natural character of an area usually accompanies the decision to manage it for maximum production of such crops as timber or range forage. Thus, if a forested area is to be managed for maximum timber production, establishment of fast-growing species of trees that will make the most efficient use of the soils, water, and climate is necessary. Crops of timber or other wood products are cut and removed regularly and other trees planted in their place, usually from nursery stock. Roads and other facilities are constructed to facilitate the removal or protection of the forest products. The ultimate objective is usually a high-yielding plantation or tree farm, often using exotic species of trees or specially developed varieties that combine high-yielding capabilities with resistance to insect pests or diseases.

Seldom do such forests have any value for other purposes, except possibly for soil protection and water yield. Aesthetically, such a forest may even lose its wild aspect and have all the regularity and artificiality of an orchard or cornfield. Recreational uses often are discouraged; even

if they are not, the recreational appeal of such areas usually is slight. Few if any of the larger forms of wild animal life can find a suitable habitat in a forest plantation, and those that do become established there often are regarded as pests if they interfere in any way with tree production. Such forests, however, produce far more timber, pulp, and other kinds of wood products than can be obtained from an equivalent area of wild forest. Moreover, intensive development of production forests in suitable locations can spare areas of natural forest for other purposes. Privately owned forests in North America are increasingly managed in this way, a practice that increases with the demand for forest products; government-owned production forests and forest plantations in other countries receive similar treatment. Such intensive development, however, is economically feasible only at sites with soils and other habitat conditions favourable to high yields.

Livestock production. Management of range and pasture lands for livestock production can become almost a single-purpose use of the land. A range, any area of wildland that is covered with natural vegetation, is usually located in the more arid mountainous or colder regions of a country; such land is suitable for the production of the larger grazing or browsing animals. Pastures, on the other hand, are grazing areas with better growing conditions than ranges because they are located either in regions of higher rainfall or in areas suitable for irrigation. Because of the nature of pasture, more intensive management is economically practical, including regular cultivation and planting to replace the natural vegetation with higher yielding domestic, exotic, or artificially bred varieties of forage plants. Livestock production on pastures is a single-purpose use of the land, although pastures are often included as part of a rotation system in the raising of farm crops. The intensive use and management of pastures effectively removes such areas from the category of wildland.

Range and pasture as single-purpose use of land

Management of the forage on rangelands requires skillful manipulation of natural processes of plant succession and the balancing of livestock numbers to the carrying capacity of the vegetation; that is, the number of animals the vegetation can support without deteriorating and endangering its future productivity. Efforts are made to avoid overgrazing, which reduces the vegetation to a less productive state, and excessive trampling by animals, which can compact the soil and interfere with its water relationships and productivity. A flexible method of livestock handling is essential to success on ranges: animals are not allowed to concentrate excessively in any one area, and their use of vegetation must be consistent with continued production of the more nutritious and palatable forage plants. Moreover, during dry periods, when there is low forage production, the number of livestock using a range must be reduced in order to avoid damage to the range; otherwise, feed lots are provided or the animals are moved to irrigated pastures.

As a primary use of rangeland, livestock production requires the construction of various facilities—fences, water holes, corrals, roads, and troughs for salt or other forage supplements. On productive rangelands it may be economically profitable to provide fertilizers, usually by spraying or dusting from aircraft, to encourage higher forage yields. Undesirable vegetation is sometimes burned, crushed, or sprayed with herbicide to provide more space for the better forage plants; ranges also may be seeded with higher yielding or more disease-resistant forage plants. Such activities necessarily restrict use of the land for other purposes. Nevertheless, except in cases of intensive management, rangelands can provide recreation and often are highly suited to various forms of wildlife management. There is considerable evidence from many parts of the world that some combination of domestic animals and wildlife can provide greater yields and profits from drier, colder, or steeper rangelands than can be obtained from such lands when used exclusively for domestic-livestock production.

Agricultural management. The most intensive forms of rural land use for agricultural purposes are those concerned with the raising of harvestable crops or with the production of animal products. Unlike primitive agriculture, which involved only the temporary removal of natural vegetation and depended for a short period of time on natural soil fertility, conventional agriculture today uses large inputs of chemicals, energy, and technical skills to produce increased yields of crops or animals. In the technologically advanced countries food production is often greater than population growth, and it is possible to retire former farmlands from use and to produce crops according to demand without approaching the maximum yields obtainable. The so-called Green Revolution has been based on the spread of such farming methods to less developed nations of the world. It has been made possible by the breeding of high-yielding forms of grain specifically adapted to the ecological conditions of the countries involved.

Green Revolution

The decision to use an area of land for high-yield agriculture essentially rules out its use for other purposes. The intensive production of farm crops in an agricultural region may also have undesirable side effects; as has been previously noted, these may include the pollution of other areas when the pesticides, herbicides, or other agricultural chemicals blown or washed from farmlands affect vegetation and animal life elsewhere. Nevertheless, committing an area to intensive agricultural production does not rule out its future restoration for other uses. As long as the soils are well cared for, such areas can be converted quickly to other purposes if it is not necessary to keep them in farm production. Abandoned farmlands in the southern United States, for example, are now highly productive forest areas, and former farming lands elsewhere are being used to support wildlife and outdoor recreation. In general planning for conservation of natural resources, intensive use and high production in those areas best suited for farming must be encouraged—provided, of course, that the polluting effects of these activities on the general environment are avoided. Such concentration can spare the destruction of other resources through attempts to use inadequate lands for marginal farming activities.

INTERNATIONAL PROBLEMS OF RESOURCE MANAGEMENT

The management of living resources requires a high degree of international cooperation and a willingness on the part of nations to agree to some forms of international control. This is particularly true for the management of those aquatic animals that occupy international waters; it is equally true for migratory animals that move from one country to another. Furthermore, the animals and plants that are commodities in international trade must also be protected through international agreements. Finally, when an international agency or an agency from a particular country works with the resources of a less developed nation in an effort to help that nation improve its economy, care is taken to avoid any adverse effects on the conservation of that nation's environment.

Despite general recognition of these problems, few nations have shown a willingness to forgo any of their sovereign rights or to cede authority over their affairs to international bodies. International laws and regulations remain, for the most part, gentlemen's agreements among nations. A country can and often does ignore the rules when it is economically advantageous for it to do so. Only international public opinion or, more rarely, the threat of force by one nation or by a group of nations can serve as an effective deterrent in compelling a country to stop certain activities that are endangering a resource. Yet, despite the generally chaotic state of international rules governing the management of environmental resources, there are some excellent international agreements concerning this matter. Such agreements provide hope that the general field of conservation may serve as an area in which nations can learn to work together more effectively for their mutual benefit.

Problems in enforcing international conservation regulations

Effective international agreements. *The Antarctic Treaty.* The Antarctic continent remained unknown and unexplored during the period when most other parts of the world were being claimed and colonized by European powers. Uninhabited and, until recently, of little or no value to any country, Antarctica never became an area for international dispute. Although segments of the continent and sub-Antarctic islands have been claimed by various nations, including the United States, Great Britain, Australia, New Zealand, Chile, and Argentina, the validity of these claims has never been tested. It was not until the latter half of the 20th century that the potential future importance of Antarctica and the knowledge to be gained from scientific research in and exploration of the continent were recognized. As a consequence, nations with an interest in Antarctica signed the Antarctic Treaty in 1961. This could be considered de facto establishment of the Antarctic continent as the world's largest strict nature reserve. The treaty provided for joint scientific research to be conducted by the signatory nations, with the results to be shared by all. It also prohibited the exploitation by any one nation of living Antarctic resources as well as any activities that would cause deterioration of those resources. The treaty has been respected, Antarctic research has gone forward, and the wild animals and sparse plant life of the continent have been protected.

Whaling agreement. Unfortunately, most agreements covering the Antarctic have not included the oceans surrounding the continent. The value of the animal resources in these waters has been known since the 18th century, and exploitation of them was begun during the 19th century. Of particular importance were the enormous herds of whales that congregated in the Antarctic seas to feed upon the abundant plankton in these nutrient-rich waters. One component of this plankton is the krill, a shrimplike crustacean; the Antarctic Treaty nations established a protective zone around the ocean waters of the continent in 1982 in an effort to preserve the krill and other marine organisms.

The early whaling ships concentrated their efforts on the larger whales, which could yield the greatest quantities of whale oil, whalebone, and other useful products. The most sought after of these creatures, the blue whale, is the world's largest mammal. It is estimated that when whaling began there were 200,000 blue whales in the Antarctic; by 1965, however, the population of blues had been reduced to about 2,000. Preceding the period of concentration on blue whales, whalers had pursued the various species of right whales in the world's oceans and had reduced their numbers to a similar low level. The gray whale of the Pacific was also brought to a point of near-extinction. The efforts of Antarctic whalers then shifted to smaller species; the humpback, once abundant, was reduced to an estimated 1,000 in 1962. Fin whales and sperm whales also bore the brunt of whaling pressure for a time; when they became scarce, the still smaller sei and Minke whales were killed.

Slaughter of blues and other whales

Despite the efforts of conservationists, attempts to restrict the activities of whalers met with little initial success. As whale populations dwindled and the danger of extinction became evident, however, the principal whaling nations agreed to sign the International Whaling Convention in 1946. This led to the establishment of the International Whaling Commission, which was authorized to sponsor scientific studies of whale populations and to recommend to the whaling nations limitations on harvest that were necessary to perpetuate whale populations and the whaling industry. Because the nations involved did not give the commission any firm power or enforcement authority, any nation could dispute the recommendations of the commission's scientific advisers and insist upon higher quotas than had been recommended. Everything depended on the willingness of the nations to obey the rules and to report honestly the number of each species of whales taken during the whaling season. Although there is no evidence that the nations involved deliberately disobeyed the recommendations finally agreed upon by the commission or that they failed to provide the commission with anything but accurate figures, the number of whales continued to decline. Sustained pressure from conservation interests, however, finally accomplished results. After 1967 the endangered whales—the blue, right, gray, and humpback—were given complete protection. Starting in the 1970s, quotas for other species were reduced to limits that enabled the whales to maintain their populations at certain levels. At its 1983 meeting the commission, over the objections of Japan, Norway, and the Soviet Union, agreed to end commercial whaling entirely by 1986; nevertheless, whaling continued after the deadline—though at a reduced level. Thus, the record of international cooperation provided by the International Whaling Convention is a mixed one. Although it did not accomplish all the desired results, neither did it fail entirely. Indeed, the record of whale conservation would be much worse had it not been for this international agreement.

Protection of fur seals and migratory birds. Other activities intended to control the international exploitation of environmental resources have had some successes and many failures. Among the most successful treaties has been one to protect the northern fur seal, a species that breeds in the Pribilof Islands, in the Bering Sea. During

The fur seal treaties

the 19th century fur seals were reduced to a dangerously low level as a result of the heavy slaughter at their breeding grounds to obtain skins for the manufacture of fur coats and various other sealskin products. In 1911 Canada, Japan, Russia, and the United States signed a treaty to limit the annual harvest of seals to a quantity that would not only sustain the population but also increase it annually. In addition, the profits from sealing were to be divided proportionately among the signatory nations. The treaty was adhered to; the seals have increased and now stock the available breeding grounds.

A good example of an international agreement governing the conservation of species that migrate between two or more nations is the International Migratory Bird Treaty. Established in 1918 between the United States and Canada, this treaty was subsequently extended to include Mexico. The treaty, which has been adhered to by the nations concerned, limits the kill of migratory waterfowl. It also provides for the protection of migratory species in their breeding grounds, along their migration routes, and at their wintering areas.

Territorial limits and marine resources. For the most part, international control of species occupying habitats in international and national waters remained a serious problem in the 20th century. The traditional three-mile agreement was loosely agreed upon by most coastal countries for military reasons: it evolved in the days when that distance was beyond the range of shells fired from guns aboard vessels offshore. The advent of large naval guns capable of firing shells three miles or more and the dominant role of naval air power during World War II made the three-mile limit useless for defense. Disputes over fishing rights led to a more general acceptance of a 12-mile (22-kilometre) limit to the seaward boundaries of national territories, but even this was not acceptable to many countries with limited coastlines or narrow continental shelves. Many Latin-American countries insisted on jurisdiction over waters to a distance of 200 nautical miles (370 kilometres) from their shores.

These disputes over national jurisdictions, combined with the desire by many countries to further exploit the marine and mineral resources of the continental shelves and deep-ocean floors, led to the first United Nations Law of the Sea Conference in 1958 to negotiate the partitioning of the oceans and their resources. A second conference was convened in 1960, but neither meeting succeeded in reaching an agreement. The Third Law of the Sea Conference was convened in 1973, and it met in numerous sessions during the 1970s and early 1980s. Finally in 1982 the Convention of the Law of the Sea was promulgated by a UN conference. The convention was quickly signed by 117 nations, but the United States and some 20 other, chiefly industrial, countries did not sign the agreement. The nonadopting nations, however, do agree that each coastal state has sovereign rights over a 12-mile territorial sea and sovereign rights over natural resources and certain economic activities within a 200-mile exclusive economic zone (EEZ). Ships are allowed innocent passage through the territorial sea, and ships and aircraft are allowed transit passage through straits used for international navigation. Coastal states also have sovereign rights regarding exploration and exploitation of the continental shelf (200 miles from shore and in some cases farther). Provision is made for delimitation of the territorial sea, EEZ, and continental shelf of archipelagic states and for access to the sea for landlocked nations. A large number of countries, including the United States, have proclaimed their sovereignty over the EEZ and the marine and mineral resources within it.

International trade in animals and plants. Special problems are involved in the regulation of trade and commerce in living animals and plants as well as in the products derived from them. Demands by wealthy nations for certain animal and plant products create particularly severe problems in less affluent countries. As mentioned previously, the trade in endangered species of wildlife is illustrative.

Furs and skins for the fashion market

The demand for furs and skins of rare animal species is artificially created in the fashion centres of the world. Prices paid by wealthy people for these items in affluent countries exceed the lifetime income of most people in the countries from which the leopards, crocodiles, tigers, and other wild species come. Poachers go to great lengths to obtain these animals wherever they can be found, including inside national parks and reserves. Because effective policing is virtually impossible, legal and illegal trade in wildlife begin to overlap, and both become firmly established. Exporters of wild animals and their products are the end links of profitable business chains that include far greater numbers of hunters and trappers in remote areas. Furthermore, for each animal or skin that reaches a foreign market, many more are destroyed in hunting, trapping, and transporting.

The purchasing countries can most effectively control the illegal trade in wildlife. This can be done by directing fashion away from the use of wild furs and by restricting the purchase of live animals and controlling their clearance through customs offices of international airports and seaports. In 1973 representatives of 80 countries signed the Convention on International Trade in Endangered Species of Wild Fauna and Flora, which prohibited commercial trade in 375 endangered species of wild animals. The treaty, which has been ratified by nearly all of the 80 governments, forbids trade in products derived from the animals (*e.g.,* hides) as well as in living animals. In addition, trade in 239 species was allowable only on the granting of permits by both the importing and the exporting countries. The provisions also included endangered plants (such as rare orchids that are now being removed from even the remotest tropical forests).

Perhaps even more serious than the trade in wild animal species is the international exploitation of other living resources, particularly the tropical forests of the world. These forests, which contain many hundreds of species of trees growing in diverse mixtures, were spared from exploitation in earlier decades because of their inaccessibility, the relatively low value of most of the trees for timber purposes, and the limited world demand. Heavily exploited for special uses were a few species of high value, such as teak, ebony, sandalwood, mahogany, and other furniture woods. Most tropical forests were not greatly disturbed, however. This situation has changed, and a wide variety of woods previously considered worthless are used for pulp, chipboard, and fibreboard or as cellulose for plastics production. With new machines and better transportation, it has become profitable to remove trees from previously remote areas and to ship logs, bolts, wood chips, or other partially processed materials to foreign markets. Faced with a high demand for their forest products, most developing nations have been willing to sign over timber rights to foreign companies, hoping thereby to increase their national incomes and to advance the general material welfare of their people. Unfortunately, most of these timber contracts contain few or no provisions for conservation. Forest industries that have excellent management and conservation records in their home countries behave differently in other lands. Great areas of tropical forest have been laid waste, soils bared to erosion, and the wildlife within them destroyed. Because no laws are violated in either the exploited or the home country, there is no effective redress. General international agreements governing the conservation of such living resources would provide an answer to this problem, but they are unlikely to be implemented in time to prevent the devastation of large areas of the tropical world.

Unintended side effects of international assistance

Equally if not more unfortunate have been the side effects of some well-intentioned international development projects. These are sometimes sponsored by international agencies concerned with such affairs and sometimes by the foreign-assistance departments of individual donor nations. Usually the projects are intended to benefit one segment of the economy of the recipient nation; but, because ecological advice generally is not sought and because of the broad effect of the proposed development on other resources or on the total environment, the side effects of some of these activities often far outweigh any benefits that are derived. An example is the Aswān High Dam of Egypt, where the need to increase the supply of water for irrigation and power was considered paramount. The environmental side effects, however, have been enormous

and include the spread of the disease schistosomiasis by snails that live in the irrigation channels, loss of land in the delta of the Nile River from erosion once the former sediment load of the river was no longer available for land building, and a variety of other consequences. Furthermore, water-development projects in other semiarid lands of Africa, sponsored by international agencies and funded by various donor organizations, have quite frequently been far more destructive than constructive. Failure to take ecological and social factors into consideration has resulted repeatedly in overgrazing and creation of deserts in an area intended to be improved by the expenditure of money. The responsibility of agencies concerned with international development to seek the best environmental advice is now generally accepted, but implementation of this responsibility has been slow.

Extraterrestrial conservation. Space exploration has begun at a time when the willingness to manage the Earth's resources is in doubt. Experiences gained from early space efforts, however, have helped promote an awareness of planetary realities among a growing number of people. The need to provide the requirements of life to people confined for long periods of time in spaceships and the problems of waste disposal in such vehicles have cast new light on similar problems within communities on Earth. The view of Earth from outer space has engendered the concept that the planet is, in effect, a large spaceship with a limited capacity to support life and that it is highly vulnerable to damage from poorly planned human activities.

Spaceship Earth

Exploration of other planets has been undertaken in full realization of the dangers involved, both in the pollution of a satellite or planet being visited by earthlings and in the potential danger to life on Earth by materials brought back from other celestial bodies. Although there is no reason to expect the existence of life on those planets nearest the Earth and every reason to doubt its existence on planets farther away in the solar system, the most rigid precautions are still necessary. Experience with the rapid spread of diseases in new locations has demonstrated the dangers to other forms of life if other planets were to be contaminated with organisms brought from Earth or if Earth were to be exposed to agents from other planets capable of contaminating life on this one.

If planets capable of supporting life are reached someday, they will offer an opportunity to science never before available. The study of life that has evolved under different conditions in a different world could add greatly to an understanding of the Earth's biologic systems as well as provide a great intellectual challenge to mankind.

THE POLLUTION OF NATURAL RESOURCES

Although various problems related to pollution of the environment have already been mentioned, the following is a more general discussion of pollution as a phenomenon.

Definition of pollution

Pollution may be defined as the addition of any substance or form of energy (*e.g.*, heat, sound, radioactivity) to the environment at a rate faster than the environment can accommodate it by dispersion, breakdown, recycling, or storage in some harmless form. A pollutant need not be harmful in itself. Carbon dioxide, for example, is a normal component of the atmosphere and a by-product of respiration that is found in all animal tissues; yet in a concentrated form it can kill animals. Human sewage can be a useful fertilizer, but when concentrated too highly it becomes a serious pollutant, menacing health and causing the depletion of oxygen in bodies of water. By contrast, radioactivity in any quantity is harmful to life, despite the fact that it occurs normally in the environment as so-called background radiation.

Pollution has accompanied mankind ever since groups of people first congregated and remained for a long time in any one place. Primitive human settlements can be recognized by their pollutants—shell mounds and rubble heaps. But pollution was not a serious problem as long as there was enough space available for each individual or group. With the establishment of permanent human settlements by great numbers of people, however, pollution became a problem and has remained one ever since. Cities of ancient times were often noxious places, fouled by human wastes and debris. In the Middle Ages, unsanitary urban conditions favoured the outbreak of population-decimating epidemics. During the 19th century, water and air pollution and the accumulation of solid wastes were largely the problems of only a few large cities. But, with the rise of advanced technology and with the rapid spread of industrialization and the concomitant increase in human populations to unprecedented levels, pollution has become a universal problem.

The various kinds of pollution are most conveniently considered under three headings: air, water, and land.

Air pollution. Air pollution involves the release into the atmosphere of gases, finely divided solids, or finely dispersed liquid aerosols at rates that exceed the capacity of the atmosphere to dissipate them or to dispose of them through incorporation into solid or liquid layers of the biosphere. Air pollution results from a variety of causes, not all of which are within human control. Dust storms in desert areas and smoke from forest and grass fires contribute to chemical and particulate pollution of the air. Forest fires that swept the state of Victoria, in Australia, in 1939 caused observable air pollution in Queensland, more than 2,000 miles (3,000 kilometres) away. Dust blown from the Sahara has been detected in West Indian islands. The discovery of pesticides in Antarctica, where they have never been used, suggests the extent to which aerial transport can carry pollutants from one place to another. Probably the most important natural source of air pollution is volcanic activity, which at times pours great amounts of ash and toxic fumes into the atmosphere. The eruptions of such volcanoes as Krakatoa, in the East Indies, Mt. St. Helens, in Washington, and Katmai, in Alaska, have been related to measurable climatic changes.

Air pollution may affect humans directly, causing a smarting of the eyes or coughing. More indirectly, the effects of air pollution are experienced at considerable distances from the source, as, for example, the fallout of tetraethyl lead from urban automobile exhausts, which has been observed in the oceans and on the Greenland ice sheet. Still less directly experienced are the possible effects of air pollution on global climates.

Urban air pollution. It is the immediate effect of air pollution on urban atmospheres that is most noticeable and causes the strongest public reaction. The city of Los Angeles has been noted for both the extent of its air pollution and the actions undertaken for control. Los Angeles lies in a coastal plain, surrounded by mountains that restrict the inward sweep of air and that separate a desert from the coastal climate. Fog moving in from the ocean is normal to the city. Temperature inversions characterized by the establishment of a layer of warm air on top of a layer of cooler air prevent the air near the ground from rising and thus effectively trap pollutants that have accumulated in the lower layer of air. In the 1940s, the air in Los Angeles became noticeably polluted, interfering with visibility and causing human discomfort. Attempts to control pollution, initiated during the 1950s, resulted in the successful elimination of such sources of pollution as industrial effluents and the outdoor burning of trash and debris. Nevertheless, pollution continued to increase as a result of the increased number of motor vehicles. Exhaust fumes from the engines of automobiles contain a number of polluting substances, including carbon monoxide and a variety of complex hydrocarbons, nitrogen oxides, and other compounds. When acted upon by sunlight, these substances undergo a change in composition producing the brown, photochemical smog for which Los Angeles is well known. Efforts to reduce pollution from automobile engines and to develop pollution-free engines may eventually eliminate the more serious air pollution problems. In the meantime, however, air pollution has driven many forms of agriculture from the Los Angeles basin, has had a serious effect upon the pine forests in nearby mountains, and has caused respiratory distress, particularly in children, elderly people, and those suffering from respiratory diseases.

The air pollution problem of Los Angeles

Los Angeles is neither a unique nor the worst example of polluted air. Tokyo has such a serious air-pollution problem that oxygen is supplied to policemen who direct

traffic at busy intersections. Milan, Ankara, Mexico City, and Buenos Aires face similar problems. Although New York City produces greater quantities of pollutants than Los Angeles, it has been spared from an air-pollution disaster only because of favourable climatic circumstances.

The task of cleaning up air pollution, though difficult, is not believed to be insurmountable. Use of fuels that are low in pollutants, such as low-sulfur forms of petroleum; more complete burning of fossil fuels, at best to carbon dioxide and water; the scrubbing of industrial smokestacks or precipitation of pollutants from them, often in combination with a recycling of the pollutants; and the shift to less polluting forms of power generation, such as solar energy in place of fossil fuels—all are methods that can be used for controlling pollution. The example of London, as well as of other cities, has shown that major improvements in air quality can be achieved in 10 years or less.

Climatic effects of polluted air. Less obvious than local concentrations of pollution but potentially more important are the climatic effects of air pollutants. Thus, as a result of the growing worldwide consumption of fossil fuels, atmospheric carbon dioxide levels have increased steadily since 1900, and the rate of increase is accelerating. The output of carbon dioxide is believed by some to have reached a point such that it may exceed both the capacity of plant life to remove it from the atmosphere and the rate at which it goes into solution in the oceans. In the atmosphere carbon dioxide creates a "greenhouse effect."

The "greenhouse effect"

Like glass in a greenhouse, it allows light rays from the Sun to pass through, but it does not allow the escape of the heat rays generated when sunlight is absorbed by the surface of the ground. An increase in carbon dioxide, therefore, can cause an increase in the temperature of the lower atmosphere. If allowed to continue, this could cause melting of the polar ice caps, raising of the sea level, and flooding of the coastal areas of the world. There is every reason to fear that such a climatic change may take place.

Counterbalancing the effect of carbon dioxide is the increase of particulate matter in the air, a result of the output of smoke, dust, and other solids associated with human activity. Such an increase might, in turn, increase the reflectance, or albedo, of the atmosphere, causing a higher percentage of solar radiation to be reflected back into space. This, in time, could cause a lowering of the Earth's surface temperature and, potentially, a new ice age. At present, however, the greater danger appears to lie in the steady increase in carbon dioxide, with its associated atmospheric warming.

Scientists also fear that the ozonosphere (or ozone layer of the atmosphere) is being depleted by the chemical action of chlorofluorocarbons emitted from aerosol cans and refrigerators and by pollutants from rockets and supersonic aircraft. Depletion of the ozone layer, which absorbs ultraviolet radiation from the Sun, would have serious effects on living organisms on the Earth's surface, including increasing frequency of skin cancer among humans.

Acid rain

Another climatic effect of pollution is acid rain. The phenomenon occurs when sulfur dioxide and nitrogen oxides from the burning of fossil fuels combine with water vapour in the atmosphere. The resulting precipitation is damaging to water, forest, and soil resources. It is blamed for the disappearance of fish from many lakes in the Adirondacks, for the widespread death of forests in European mountains, and for damaging tree growth in the United States and Canada. Reports also indicate that it can corrode buildings and be hazardous to human health. Because the contaminants are carried long distances, the sources of acid rain are difficult to pinpoint and hence difficult to control. Acid rain has been reported in areas as far apart as Sweden and Canada, and in parts of the United States from New England to Texas. The drifting of pollutants causing acid rain across international boundaries has created disagreements between Canada and the United States and among European countries over the causes and solutions of the precipitation. The international scope of the problem has led to the signing of international agreements on the limitation of sulfur and nitrogen oxide emissions.

Radioactive contamination of the atmosphere. During the 1950s the effects of atmospheric testing of atomic and hydrogen bombs became a source of major concern. The danger of radioactive pollution of the air and the fallout of radioactive particles to the surface of the Earth stimulated serious investigation, resulting in the discovery of potentially dangerous conditions. It was observed, for example, that radioactive materials of many kinds, such as radioactive iodine and strontium, are concentrated in living tissue and can cause damage even when the general level of environmental contamination is low. Atmospheric testing of nuclear bombs was stopped in the United States and the Soviet Union, and radioactive fallout from this source has declined. Concern continues, however, over the dangers resulting from massive releases of radioactive materials from nuclear weapons, which, if used on a major scale, could seriously endanger all of humanity.

Another concern is accidents at nuclear power plants. In 1978 the Three Mile Island nuclear power plant in Pennsylvania suffered a severe accident leading to partial meltdown of its radioactive core. Although most of the radiation was contained within the plant structure, the prospects of massive contamination of nearby cities and towns resulted in plans for the evacuation of hundreds of thousands of people. In 1986 the Chernobyl nuclear power plant near Kiev, in the Ukrainian S.S.R., suffered a fire and partial meltdown, resulting in a major release of radioactive particles. Much of northern and eastern Europe experienced heavy nuclear fallout, and the towns and farmlands around the power plant were no longer safe for human occupancy.

Water pollution. Water pollution involves the release into lakes, streams, rivers, and oceans of substances that become dissolved or suspended in the water or deposited upon the bottom and accumulate to the extent that they interfere with the functioning of aquatic ecosystems. It may also include the release of energy in the form of radioactivity or heat, as in the case of thermal pollution. Any body of water has the capacity to absorb, break down, or recycle introduced materials. Under normal circumstances, inorganic substances are widely dispersed and have little or no effect on life within the bodies of water into which they are released; organic materials are broken down by bacteria or other organisms and converted into a form in which they are useful to aquatic life. But, if the capacity of a body of water to dissolve, disperse, or recycle is exceeded, all additional substances or forms of energy become pollutants. Thus, thermal pollution, which is usually caused by the discharge of water that has been used as a coolant in fossil-fueled or nuclear-power plants, can favour a diversity of aquatic life in waters that would otherwise be too cold. In a warmer body of water, however, the addition of heat changes its characteristics and may make it less suited to species that are considered desirable.

Thermal pollution of water

Pollution may begin as water moves through the air, if the air is polluted. Soil erosion adds silt as a pollutant. The use of chemical fertilizers, pesticides, or other materials on watershed lands is an additional factor contributing to water pollution. The runoff from septic tanks and the outflow of manures from livestock feedlots along the watershed are sources of organic pollutants. Industries located along waterways downstream contribute a number of chemical pollutants, some of which are toxic if present in any concentration. Finally, cities and towns contribute their loads of sewage and other urban wastes. Thus, a community far upstream in a watershed may receive relatively clean water, whereas one farther downstream receives a partly diluted mixture of urban, industrial, and rural wastes. The cost of cleaning and purifying this water for community use may be high, and the process may be only partially effective. To add to the problem, the cities and towns in the lower, or downstream, regions of the river basin contribute additional wastes that flow into estuaries, creating new pollution problems.

The output of industries, agriculture, and urban communities generally exceeds the biologic capacities of aquatic systems, causing waters to become choked with an excess of organic substances and organisms to be poisoned by toxic materials. When organic matter exceeds the capacity of those microorganisms in water that break it down and recycle it, the excess of nutrients in such matter encour-

ages rapid growth, or blooms, of algae. When they die, the remains of the dead algae add further to the organic wastes already in the water; eventually, the water becomes deficient in oxygen. Anaerobic organisms (those that do not require oxygen to live) then attack the organic wastes, releasing gases such as methane and hydrogen sulfide, which are harmful to the oxygen-requiring (aerobic) forms of life. The result is a foul-smelling, waste-filled body of water, a situation that has already occurred in such places as Lake Erie and the Baltic Sea and is a growing problem in freshwater lakes of Europe and North America. The process by which a lake or any other body of water changes from a clean, clear condition—with a relatively low concentration of dissolved nutrients and a balanced aquatic community—to a nutrient-rich, algae-filled body and thence to an oxygen-deficient, waste-filled condition is known as accelerated eutrophication.

Eutrophication of bodies of water

Land pollution. Land pollution involves the deposition on land of solid wastes—*e.g.,* used cars, cans, bottles, plastic containers, paper—that cannot be broken down quickly or, in some instances, cannot be broken down at all by the action of organic or inorganic forces. (The term biodegradable is used to describe those materials that can be decomposed and recycled by biological action.) When such materials become concentrated within any one area, they interfere with organic life and create unsightly accumulations of trash. Methods of disposal other than recycling include ocean dumping, which creates water pollution and destroys marine habitats; landfill, which often requires the availability of low-lying ground and frequently involves the destruction of marshland or swamps that have high biological value; and burning, which increases air pollution. Obviously, none of these methods is entirely satisfactory, although using landfill to create artificial landscapes, which then are covered with soil and planted with various kinds of vegetation, is a possibility that remains to be fully developed. It is the great quantity of debris produced by urban communities, more so than a shortage of raw materials, that forces the development of more effective means for recycling wastes. Land pollution also involves the accumulation on land of substances in dispersed solid or liquid form that are injurious to life. This has been particularly noticeable with those chemicals (*e.g.,* DDT) that are spread for the purpose of exterminating pests but then accumulate to the extent that they can do damage to many other forms of life.

Noise pollution. One form of pollution that is characteristic of industrial societies is noise. The intensity of sound is measured in logarithmic units known as decibels; a change from a level of 10 decibels to one of 20 decibels actually represents a 100-fold increase in the sound level. At a level of 80 decibels, sound is annoying; but steady exposure to noise in excess of 90 decibels—a level that is frequently exceeded by many common urban sounds, such as jackhammers, jet planes, and excessively loud music—can cause permanent loss of hearing. In addition to causing loss of hearing, there is some evidence that noise can produce other deleterious effects on human health and on work performance.

Many large cities have taken measures to decrease the level of urban noise; the problem has received much attention with the advent of supersonic jet airplanes. These aircraft, which travel at speeds faster than the speed of sound, create sound waves (sonic booms) equivalent to those of major explosions and capable of damaging structures. The extent to which continuous exposure to sonic booms affects human health and functioning has yet to be determined. Nevertheless, in 1971 the U.S. Congress voted down appropriations to support the development of supersonic transport (SST) planes; several countries, including Britain and France, however, have manufactured such aircraft.

Sonic booms

Chemical pollutants. Among the most serious chemical pollutants are the chlorinated hydrocarbon pesticides, such as DDT, aldrin, and dieldrin; the polychlorinated biphenyls (PCBs), which are used in a variety of industrial processes and in the manufacture of many kinds of materials; and such metals as mercury, lead, cadmium, arsenic, and beryllium. All of these substances persist in the environment, being slowly, if at all, degraded by natural processes; in addition, all are toxic to life if they accumulate in any appreciable quantity.

The persistent pesticides have created serious ecological problems. As they move through successively higher organisms in food chains, they accumulate in increasingly concentrated forms at each level, causing damaging effects to the predators at the end of the chains—*i.e.,* they are present in low quantities in simple organisms but become more concentrated as these organisms are consumed by more complex ones, which are themselves consumed by predators. Among the species known to be adversely affected are such meat-eating birds as falcons, hawks, and eagles and such fish-eating birds as pelicans, petrels, cormorants, and egrets. The reproduction capacity of all of these birds has been affected by an accumulation of DDT or a similar compound in their tissues. This is manifested by an impairment in the ability of the females to form eggshells properly. As a result, some species lay soft-shelled or shell-less eggs that cannot be hatched, and there has been a general decline in the numbers of these birds in Europe, Japan, and North America. Although the effects of the same chemicals on mammals is less obvious and still a matter for investigation, some studies suggest that DDT can reduce the productivity of plant plankton, upon which all other marine life depends.

There also is substantial evidence that pesticides lose the ability to control the pests they were designed to kill. Many insect species have developed immunity to a wide range of synthetic pesticides, and the resistance is inherited by their offspring. Furthermore, it has been observed that repeated use of such chemicals creates pest populations in areas in which none previously existed. This happens because the pesticides destroy populations of carnivorous, predatory insects that had in the past kept the plant-eating insects in check.

Among other materials that are harmful to most forms of life are such metals as mercury, lead, and arsenic. The increasing release of these substances into the biosphere by industrial processes has created conditions that are now generally viewed as harmful to human welfare. Studies have been conducted on metallic pollutants to determine the normal environmental levels, the levels that are toxic to humans, and the extent to which industrial processes are responsible for the problem.

The ultimate control of pollution will presumably involve the decision not to allow the escape into the environment of the substances that are harmful to life, the decision to contain and recycle those substances that could be harmful if released into the environment in excessive quantities, and the decision not to release into the environment substances that persist and are toxic to living things. Essentially, therefore, pollution control does not mean an abandonment of existing productive human activities but their reordering so as to guarantee that their side effects do not outweigh their advantages.

CONSERVATION AND GROWTH

The Earth has supported human civilization for more than 6,000 years and agriculture for twice that period. Before that, reaching back an unmeasured number of years into the past, human or near-human groups occupied various parts of the Earth, modifying them to some degree in the course of hunting, fishing, and food gathering. Patterns of land use were determined over many centuries of trial-and-error experimentation by people equipped with primitive tools who depended on the biological communities of the Earth for their energy supplies. Today, however, with abundant fossil fuels, growing amounts of nuclear energy, and sophisticated tools and machines, it is possible to quickly modify entire landscapes, changing long-established natural patterns into new patterns with new purposes. The opportunity to enhance the material welfare and general well-being of great numbers of people is now available, as is the opportunity to cause great damage and to impair the capacity of the Earth to support life. The outcome will depend on changes in attitudes toward the use and conservation of the Earth's living and nonliving resources.

Changing patterns of land use

The role of population, industry, and technology. Uses of lands and resources are being modified in the expectation of continued population growth, industrial expansion, and accelerating technological change. Yet it is possible that, in the future, uses of lands and resources will take place in times of population stability, little industrial expansion, and a technology directed toward a reorganization and a rearrangement of activities to achieve a better environmental relationship. Even though certain countries of the world have already reached some degree of population stability—*e.g.*, Ireland, Hungary, France, Sweden, Switzerland, and Japan—industrial expansion and rapid technological change continue in these countries, in part because of the demands made by other expanding nations. The existing expansionist phase of technological civilization cannot, however, be expected to continue indefinitely. The ecological limitations on growth in a limited space with limited resources lead to predictions of an inevitable end to this expansion, even if mankind fails to voluntarily limit its own growth.

Ecological considerations and advance planning. Current decisions about land and resource use have important consequences for the future. If extensive areas of the Earth are badly damaged or their productivity destroyed by the expansion of technological civilization, they will be difficult, if not impossible, to restore. If a species becomes extinct, for example, it cannot be brought back. It is essential, therefore, that care be exercised in further modifying the planet to suit human purposes. Yet in many developing regions of the world, those where the greatest changes may be expected, little attention is being given to planning for and carefully controlling the use of land and resources. Thus, important tropical, semiarid, and subpolar regions of the Earth—the three principal climatic belts that have not yet undergone major technological development—are now being changed drastically without much consideration for their environments. In many parts of the world, ecologically trained experts are not available; in others, because of strong economic pressures toward development, ecological advice either is not sought or is ignored.

Climatic belts currently being exploited

Comparatively speaking, the failure to apply current ecological knowledge to the changing land and resource use taking place in tropical, semiarid, and subarctic lands is equivalent to the modification of the more temperate lands that took place centuries ago, when ecological knowledge was not available. In earlier centuries, however, the capacity to do irreparable damage was restricted by the lack of machinery, industry, and fuel energy. Today, capabilities are such that major destruction can be accomplished quickly. There is, therefore, a need to call upon environmental expertise during the process of economic development in any area of the world if natural resources are to be conserved and the future welfare of humanity is to receive due consideration.

Some ecologists now believe that, although it was once possible to allow the development of a region to proceed more or less at random, based on individual wants, aspirations, and decisions about the use of lands and resources, such a process now holds too much risk for the well-being of society as a whole and for the future of the resources on which that society depends. Planning, they argue, must precede development, and regional planning is required if the use of major areas of land and its resources is to be brought into accord with environmental necessities and with the long-term needs of society.

In densely populated and technologically advanced nations, such as those of western and northern Europe, most of the land-use decisions that would affect large areas have already been made. Although changes do occur, mostly in relation to growing urbanization and increasing material wealth, it seems likely that the remaining woodlands and fields will continue to be devoted to their present uses. In England the interest of the central government in the planning and control of land use and population distribution was marked by the passage of the Town and Country Planning Act shortly after World War II. This legislation led to decisions to limit the growth of London and to develop a pattern of new towns outside a greenbelt of agricultural and recreational land that surrounds the metropolis. In France, where there are still large areas of open space, a system for regional planning and control of land use and development (*aménagement du territoire*) has been formulated. It has already resulted in the establishment of new cities and recreational sites in previously undeveloped areas along the Mediterranean coast.

Control of land use and population distribution

It is in the sparsely populated areas in the underdeveloped countries of Africa, Asia, and Latin America as well as in such technologically advanced countries as Canada, Australia, and Russia that the greatest range of options and choices for the future is available. Because these areas have yet to undergo drastic environmental change, the need for local and regional environmentally oriented planning for resource and land use is most urgent.

Areas of promise. Some of the current vexing conservation problems may be solved by technological developments. A highly technological society obviously requires an abundant and reliable source of energy. Research on nuclear fusion as a source of power indicates that this process could replace nuclear fission as a power source in some areas, but it appears to be too technologically demanding for widespread application. Solar energy, in its various modified forms, may be a more universally available source of power.

Apart from the development of major new sources of power, the greatest promise for the future of mineral resources and for the prevention of pollution of the environment lies in new technologies involving the recycling and reclamation of what are now considered waste products. Demands for new minerals will be greatly reduced when those already available in population centres can be reused more readily. Reclamation of sewage and other organic wastes and restoration of these materials to soils can help to arrest losses in soil fertility and structure and to reduce the need for new supplies of chemical nutrients for soil fertilization. If development of technologies for recycling and reutilization continues, many of the existing problems of environmental pollution will be solved.

In addition to the breeding of new strains of crop plants, the development of agricultural disease- and pest-control techniques that do not involve the release of persistent, poisonous chemicals into the environment holds promise for the production of greatly increased quantities of food and fibre from smaller areas of the Earth's surface. Two such techniques are mixed cropping, in which different crops are planted within an area to contain the spread of pests, and integrated pest management, in which as many pest-control methods as possible are used in an ecologically harmonious manner to keep infestation within manageable limits. Much more intensive development of aquaculture (cultivation of the natural produce of water), perhaps utilizing coolant water from nuclear-power plants, can also produce much higher food yields from smaller areas than are now usually obtainable. As a result of these advances in intensive food production, agriculturally marginal lands and the wilder aquatic areas would be spared for the continued support of wild species as well as for the adventure and recreation of mankind, thus helping to solve one of the most troublesome of all conservation problems, the conservation of wild nature.

Aquaculture for food production

Problems. Considering the potential of new technology and the accompanying advances in science, it is possible to foresee a world in which a relatively stable human population can live at a high level of material affluence, with wild nature continuing to exist in abundance and relatively undisturbed lands available for human enjoyment. But this scientific and technological optimism is not supported by existing world conditions. Because knowledge now available is more than adequate to solve most of the world's major environmental problems, the problems are not those of science and technology but of the arrangements and functioning of human institutions and of the attitudes of individuals. Thus, while research in forestry science continues in all the forestry schools of the world, tropical forests are being devastated in ways that suggest that forestry science is still unknown. Although the techniques for managing livestock on natural ranges and pasturelands have reached a high level of sophistication, overgrazing continues around most of the world's major

deserts, and animals die of hunger, people suffer from deprivation, and the deserts spread. Obviously, the knowledge available does not reach or influence the behaviour of most of the pastoral people on Earth.

Population growth. Demographic predictions indicate that the population of the world will not be stabilized, even under the best of conditions, before it attains much higher levels. These predictions assume, of course, that there will be no major catastrophes—outbreaks of war, famine, or disease—that would cause drastic reductions in human numbers. There is little doubt that rapid population growth interferes with orderly economic development, leads to a deterioration of the human environment, places a severe strain on human institutions, and constitutes a growing threat to the survival of wild animal and plant life.

Necessity for curbing birthrates

Although techniques for birth control are effective and well known, they are unknown, unavailable, or unacceptable to those people having the most rapid rate of population growth—the ones who also live in the most precarious balance with their environment. This does not mean that the prospects for controlling population increase are poor; actually, they are better than at any time in the past. But more education is needed to encourage people to limit the size of families, and the prospects for material and economic advancement for those who have fewer children must be made more obvious.

Pollution control. Next to the widespread and growing loss of biological diversity through the destruction of biotic communities, the conservation problem of greatest magnitude is the control of pollution; it might even be argued that it is more urgent and important. The knowledge and technology needed to control pollution effectively are now available: pollution-free engines can be built, pollution-free factories have been put into operation, and techniques for controlling agricultural insect pests with a minimum use of persistent pesticides have been developed. For economic reasons, none of these measures, however, is being applied universally, and political and social pressures have not yet forced their application. Moreover, developing nations have expressed fear that excessive concern over pollution could impede their economic development. Indeed, some of these countries have become sanctuaries for industries that find it less expensive to operate in areas with more lax standards. It is apparent that pollution control, regardless of the state of its technology, will become a reality only when people demand it and only when nations are willing to agree on appropriate international standards.

Control over use of resources. Important also to the future of world conservation is the failure of most societies to exercise adequate controls over land, water, and other resource use. Effective means for controlling land use do not exist in most countries; laws and regulations that permit governments to exercise such control, when existent, often cannot be enforced because of the danger of strong public resentment and resistance. Although it is essential that lands and all other resources be used with a view to preserving their future productivity, this view all too often conflicts with present needs or demands of the resource users. The solution to this conflict is not within the scope of science or technology; instead, it is a question of attitudes and values, and these are less amenable to sudden change than laws or regulations. It appears that economic security and social stability are essential for people to look beyond immediate survival to the well-being of humanity and the future of life on this planet.

BIBLIOGRAPHY

General works: *World Resources 1986* (1986), an assessment of the resource base that supports the global economy, prepared by the World Resources Institute and the International Institute for Environment and Development and including data for 146 countries; ROBERT REPETTO (ed.), *The Global Possible: Resources, Development, and the New Century* (1985), a collection of papers on current problems and prospects for the 21st century; JOHN R. HOLLUM, *Topics and Terms in Environmental Problems* (1977), a basic reference source for understanding the terminology and general subjects related to resource conservation and environmental concerns; RAYMOND F. DASMANN, *Environmental Conservation,* 5th ed. (1984), a general textbook on the conservation of natural resources, stressing their interrelationships and use; FRANK FRASER DARLING, *Wilderness and Plenty* (1970), a series of lectures, presented by the British Broadcasting Company in 1969, that had a great effect on environmental thinking in Europe; FAIRFIELD OSBORN, *Our Plundered Planet* (1948), a classic in conservation, one of the first world views of the impact of human populations and land use on the natural resources of the Earth; WILLIAM L. THOMAS (ed.), *Man's Role in Changing the Face of the Earth* (1956, reprinted 1971), a comprehensive presentation of mankind's past, present, and probable future roles on the Earth, a classic in conservation; MARTIN W. HOLDGATE, MOHAMMED KASSAS, and GILBERT F. WHITE (eds.), *The World Environment 1972–1982: A Report by the United Nations Environment Programme* (1982); *Ocean Yearbook* (annual), a collection of papers dealing with resource management of the world's oceans, fisheries, and minerals, as well as the law of the sea; JOSEPH M. MORAN, MICHAEL D. MORGAN, and JAMES H. WIERSMA, *Introduction to Environmental Science,* 2nd ed. (1986), a source of information on ecology and environmental concerns; and EDWARD O. WILSON, *Biophilia* (1984), a study of interrelationships in life and lifelike processes.

History of conservation: RODERICK NASH, *Wilderness and the American Mind,* 3rd ed. (1982), a history of changes in American attitudes toward wilderness, beginning with the Old World roots and leading to the existing system of protected wilderness areas; ALFRED W. CROSBY, *Ecological Imperialism: The Biological Expansion of Europe, 900–1900* (1986), a historical account of the impact of European trade and colonialism upon traditional peoples and the natural environment. CLARENCE J. GLACKEN, *Traces on the Rhodian Shore: Nature and Culture in Western Thought from Ancient Times to the End of the Eighteenth Century* (1967, reprinted 1976), an account of the philosophies and ideas of nature; GEORGE P. MARSH, *Man and Nature: or, Physical Geography as Modified by Human Action* (1864, reissued 1965), a classic of conservation and the first general view of how people change the Earth and affect its living resources; RODERICK NASH (ed.), *The American Environment: Readings in the History of Conservation,* 2nd ed. (1976), a review of the evolution of conservation in the United States, with readings from the works of those who contributed to its development; HENRY D. THOREAU, *Walden: or, Life in the Woods* (1854, with many later editions available), a classic philosophical exploration of humanity's relationship with nature and the values to be found in living apart from civilization and its artifacts, by one of the first advocates of wilderness preservation; MICHAEL P. COHEN, *The Pathless Way: John Muir and American Wilderness* (1984), an analysis of preservationist thought on human beings in the environment; and STEWART L. UDALL, *The Quiet Crisis* (1963, reissued 1971), a review of the history of conservation and the growing crisis in conservation, with emphasis on public lands and living resources in the United States.

Ecology: CHARLES ELTON, *Animal Ecology* (1927, reissued 1966), a classic work in ecology and the forerunner to the application of animal ecology in the management of wildlife; NORMAN MYERS, *The Sinking Ark: A New Look at the Problem of Disappearing Species* (1979, reprinted 1983), an argument for the preservation of a balance of animal species; EUGENE P. ODUM, *Fundamentals of Ecology,* 3rd ed. (1971), a standard textbook on general ecology, which emphasizes the nature and functions of ecosystems and includes a discussion of the relationships between ecology and environmental problems; J.E. LOVELOCK, *Gaia, a New Look at Life on Earth* (1979), an investigation of the hypothesis that the self-regulating biosphere forms a complex system with the capacity to keep the Earth a fit place for life; NORMAN MYERS, *Gaia, an Atlas of Planet Management* (1984), and *The Primary Source: Tropical Forests and Our Future* (1984), studies by an environmentalist; DONALD WORSTER, *Nature's Economy: A History of Ecological Ideas,* new ed. (1985), an exploration of changing ideas about ecology from the 18th century to the present and their effect on environmental management; MICHAEL E. SOULÉ (ed.), *Conservation Biology: The Science of Scarcity and Diversity* (1986), a collection of papers concerning the application of ecological knowledge and population genetics to problems of conserving threatened species and maintaining the diversity of life on Earth; and FRANCIS R. THIBODEAU and HERMANN H. FIELD (eds.), *Sustaining Tomorrow: A Strategy for World Conservation and Development* (1984), a collection of essays on topics of preservation and conservation of ecological balance.

Pollution: RACHEL CARSON, *Silent Spring* (1962, reissued 1982), a popular best-seller that first alerted the general public to the dangers inherent in the widespread use of persistent pesticides; GINO G. MARCO, ROBERT M. HOLLINGWORTH, and WILLIAM DURHAM (eds.), *Silent Spring Revisited* (1987), a collection of essays on the topics posed in Rachel Carson's book; ROBERT L. RUDD, *Pesticides and the Living Landscape* (1964, reprinted 1970), a scholarly review of the ways in which pesticides enter into the ecological networks in natural and

man-made environments, with a discussion of the dangers involved in their continued use; *Environmental Quality* (annual), a regular report of the Council on Environmental Quality, which reviews the state of the U.S. environment with particular emphasis on problems of pollution; AMERICAN CHEMICAL SOCIETY, *Cleaning Our Environment: A Chemical Perspective,* 2nd ed. (1978); a report by the Council on Environmental Improvement on the technological state of the art of pollution control; BARRY COMMONER, *Science and Survival* (1966), a discussion of how science and technology can cause unanticipated changes in the environment, with particular reference to pollution from nuclear energy; DONALD L. BARLETT and JAMES B. STEELE, *Forevermore, Nuclear Waste in America* (1985), an investigative report on the environmental hazard; and SCIENTIFIC COMMITTEE ON PROBLEMS OF THE ENVIRONMENT (SCOPE), *Environmental Consequences of Nuclear War,* 2 vol. (1985–86), an international scientific review of the likely effects of nuclear war, prepared by a committee of the International Council of Scientific Unions.

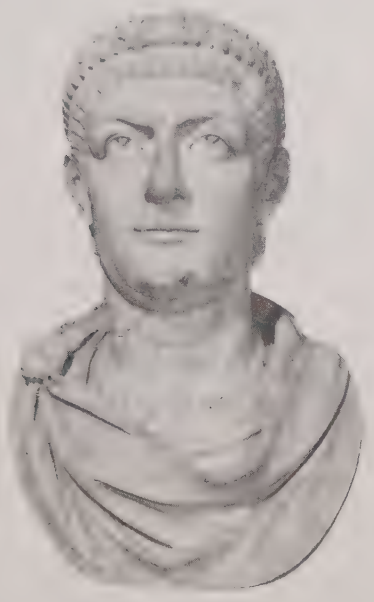
Population, resources, and technological development: PAUL R. EHRLICH, *The Population Bomb,* rev. ed. (1971, reprinted 1978), a popular book that touched off the population debates of the late 1960s and early 1970s; PAUL R. EHRLICH, ANNE H. EHRLICH, and JOHN P. HOLDREN, *Ecoscience: Population, Resources, Environment* (1977), a study providing coverage of the major environmental and resource concerns and the scientific basis for their evaluation; GERALD O. BARNEY (ed.), *The Global 2000 Report to the President: Entering the Twenty-First Century,* 3 vol. (1980–81), an analysis of natural resource and environmental problems, with a forecast of conditions in the year 2000 considering existing trends and likely changes, prepared by the Council on Environmental Quality; AMORY B. LOVINS, *Soft Energy Paths: Toward a Durable Peace* (1977), an examination of the future prospects for fossil fuels, nuclear energy, and renewable energy resources; GEORG BORGSTROM, *The Hungry Planet: The Modern World at the Edge of Famine,* 2nd rev. ed. (1972), a review of human food needs and the prospects for meeting them, with particular attention to the use of ocean resources; M. TAGHI FARVAR and JOHN P. MILTON (eds.), *The Careless Technology: Ecology and International Development: The Record* (1972), a collection of case histories and related discussions concerning the unexpected side effects of economic and technological development; and WILLIAM VOGT, *Road to Survival* (1948), a classic work on the relationship between populations and resources, written from an emotional viewpoint in an attempt to draw attention to the coming population crisis and emphasizing the growing threat of world hunger, as well as the impact of humans on soils and renewable resources.

Management of living resources: WENDELL BERRY, *The Unsettling of America: Culture & Agriculture* (1977, reprinted 1986), an examination of the past, present, and future of agricultural land use; NORMAN MYERS, *A Wealth of Wild Species: Storehouse for Human Welfare* (1983), an exposition of concerns for the necessity of maintaining genetic and biologic diversity; RAYMOND F. DASMANN, *Wildlife Biology,* 2nd ed. (1981), an introductory college textbook reviewing the principles of wildlife biology and their application to the conservation and management of wild animals; STEPHEN HADEN-GUEST, JOHN K. WRIGHT, and EILEEN M. TECLAFF (eds.), *A World Geography of Forest Resources* (1956), a survey of the forest resources of the world, the extent to which they are being used, and the problems associated with their management; G.V. JACKS and R.O. WHYTE, *Vanishing Lands: A World Survey of Soil Erosion* (1939; U.K. title, *The Rape of the Earth;* reprinted 1972), a classic work that reviews the nature of world soils and describes their destruction by erosion as a result of misuse; ALDO LEOPOLD, *Game Management* (1933, reprinted 1986), the first textbook of wildlife management, a conservation classic, and his *Sand County Almanac and Sketches Here and There* (1949, reprinted 1981), a study of the ethics and aesthetics of conservation, with emphasis on land, wildlife, and wilderness; LAURENCE A. STODDART, ARTHUR D. SMITH, and THADIS W. BOX, *Range Management,* 3rd ed. (1975), a textbook on the principles and practices affecting the use of range and pasturelands by grazing animals.

(R.F.D.)

Constantine the Great

Constantine I, the first Roman emperor to profess Christianity, not only initiated the evolution of the empire into a Christian state but also provided the impulse for a distinctively Christian culture that prepared the way for the growth of Byzantine and Western medieval culture. He was born on February 27, probably in the later AD 280s, at Naissus (modern Niš, Yugos.). A typical product of the military governing class of the later 3rd century, he was the son of Flavius Valerius Constantius, an army officer, and his wife (or concubine) Helena; his full Latin name was Flavius Valerius Constantinus. In AD 293 his father was raised to the rank of Caesar, or deputy emperor (as Constantius I Chlorus), and was sent to serve under Augustus (emperor) Maximian in the West. In 289 Constantius had separated from Helena in order to marry a stepdaughter of Maximian, and Constantine was brought up in the Eastern Empire at the court of the senior emperor Diocletian at Nicomedia (modern İzmit, Tur.). Constantine was seen as a youth by his future panegyrist, Eusebius, bishop of Caesarea, passing with Diocletian through Palestine on the way to a war in Egypt.



Constantine the Great, marble bust (restored), 4th century AD. In the Uffizi, Florence.

Career and conversion. Constantine's experience as a member of the imperial court—a Latin-speaking institution—in the Eastern provinces left a lasting imprint on him. Educated to less than the highest literary standards of the day, he was always more at home in Latin than in Greek: later in life he had the habit of delivering edifying sermons, which he would compose in Latin and pronounce in Greek from professional translations. Christianity he encountered in court circles as well as in the cities of the East; and from 303, during the great persecution of the Christians that began at the court of Diocletian at Nicomedia and was enforced with particular intensity in the eastern parts of the empire, Christianity was a major issue of public policy. It is even possible that members of Constantine's family were Christians.

In 305 the two emperors, Diocletian and Maximian, abdicated, to be succeeded by their respective deputy emperors, Galerius and Constantius. The latter were replaced by Galerius Valerius Maximinus in the East and Flavius Valerius Severus in the West, Constantine being passed over. Constantius requested his son's presence from Galerius, and Constantine made his way through the territories of the hostile Severus to join his father at Gesoriacum (modern Boulogne, Fr.). They crossed together to Britain and fought a campaign in the north before Constantius' death at Eboracum (modern York) in 306. Immediately acclaimed emperor by the army, Constantine then threw himself into a complex series of civil wars in which Maxentius, the son of Maximian, rebelled at Rome; with his father's help, Maxentius suppressed Severus, who had been proclaimed Western emperor by Galerius and who was then replaced by Licinius. When Maximian was rejected by his son, he joined Constantine in Gaul, only to betray Constantine and to be murdered or forced to commit suicide (310). Constantine, who in 307 had married Maximian's daughter Fausta as his second wife, invaded Italy in 312 and after a lightning campaign defeated his brother-in-law Maxentius at the Milvian Bridge near Rome. He then confirmed an alliance that he had already entered into with Licinius (Galerius having died in 311): Constantine became Western emperor and Licinius shared the East with his rival Maximinus. Licinius defeated Maximinus and became the sole Eastern emperor but lost territory in the Balkans to Constantine in 316. After a further period of tension, Constantine attacked Licinius in 324, routing him at Adrianople and Chrysopolis (respectively, modern Edirne and Üsküdar, Tur.) and becoming sole emperor of East and West.

Acclaimed emperor by troops

Throughout his life, Constantine ascribed his success to his conversion to Christianity and the support of the Christian God. The triumphal arch erected in his honour at Rome after the defeat of Maxentius ascribed the victory to the "inspiration of the Divinity" as well as to Constantine's own genius. A statue set up at the same time showed Constantine himself holding aloft a cross and the legend "By this saving sign I have delivered your city from the tyrant and restored liberty to the Senate and people of Rome." After his victory over Licinius in 324, Constantine wrote that he had come from the farthest shores of Britain as God's chosen instrument for the suppression of impiety, and in a letter to the Persian king Shāpūr II he proclaimed that, aided by the divine power of God, he had come to bring peace and prosperity to all lands.

Constantine's adherence to Christianity was closely associated with his rise to power. He fought the Battle of the Milvian Bridge in the name of the Christian God, having received instructions in a dream to paint the Christian monogram (☧) on his troops' shields. This is the account given by the Christian apologist Lactantius; a somewhat different version, offered by Eusebius, tells of a vision seen by Constantine during the campaign against Maxentius, in which the Christian sign appeared in the sky with the legend "In this sign, conquer." Despite the Emperor's own authority for the account, given late in life to Eusebius, it is in general more problematic than the other; but a religious experience on the march from Gaul is suggested also by a pagan orator, who in a speech of 310 referred to a vision of Apollo received by Constantine at a shrine in Gaul.

"In this sign, conquer"

Yet to suggest that Constantine's conversion was "politically motivated" means little in an age in which every Greek or Roman expected that political success followed from religious piety. The civil war itself fostered religious competition, each side enlisting its divine support, and it would be thought in no way unusual that Constantine should have sought divine help for his claim for power and divine justification for his acquisition of it. What is remarkable is Constantine's subsequent development of his new religious allegiance to a strong personal commitment.

Commitment to Christianity. Shortly after the defeat of Maxentius, Constantine met Licinius at Mediolanum (modern Milan) to confirm a number of political and dynastic arrangements. A product of this meeting has

become known as the Edict of Milan, which extended toleration to the Christians and restored any personal and corporate property that had been confiscated during the persecution. The extant copies of this decree are actually those posted by Licinius in the eastern parts of the empire. But Constantine went far beyond the joint policy agreed upon at Mediolanum. By 313 he had already donated to the Bishop of Rome the imperial property of the Lateran, where a new cathedral, the Basilica Constantiniana (now S. Giovanni in Laterano), soon rose. The Church of St. Sebastian was also probably begun at this time, and it was in these early years of his reign that Constantine began issuing laws conveying upon the church and its clergy fiscal and legal privileges and immunities from civic burdens.

Public and personal "theology"

As he said in a letter of 313 to the proconsul of Africa, the Christian clergy should not be distracted by secular offices from their religious duties ". . . for when they are free to render supreme service to the Divinity, it is evident that they confer great benefit upon the affairs of state." In another such letter, directed to the Bishop of Carthage, Constantine mentioned the Spanish bishop Hosius, who was important later in the reign as his adviser and possibly—since he may well have been with Constantine in Gaul before the campaign against Maxentius—instrumental in the conversion of the Emperor.

Constantine's personal "theology" emerges with particular clarity from a remarkable series of letters, extending from 313 to the early 320s, concerning the Donatist schism in North Africa. The Donatists maintained that those priests and bishops who had once lapsed from the Christian faith could not be readmitted to the church. Constantine's chief concern was that a divided church would offend the Christian God and so bring divine vengeance upon the Roman Empire and Constantine himself. Schism, in Constantine's view, was inspired by Satan. Its partisans were acting in defiance of the clemency of Christ, for which they might expect eternal damnation at the Last Judgment. Meanwhile, it was for the righteous members of the Christian community to show patience and long-suffering. In so doing they would be imitating Christ, and their patience would be rewarded in lieu of martyrdom—for actual martyrdom was no longer open to Christians in a time of peace for the church. Throughout, Constantine had no doubt that to remove error and to propagate the true religion were both his personal duty and a proper use of the imperial position. His claim to be "bishop of those outside the church" may be construed in this light. Other such pronouncements, expressed in letters to imperial officials and to Christian clergy, demonstrate that Constantine's commitment to Christianity was firmer and less ambiguous than some have suggested. Eusebius confirmed what Constantine himself believed: that he had a special and personal relationship with the Christian God.

Arianism and the Council of Nicaea

Constantine's second involvement in an ecclesiastical issue followed the defeat of Licinius; but the Arian heresy, with its intricate explorations of the precise nature of the Trinity that were couched in difficult Greek, was as remote from Constantine's educational background as it was from his impatient, urgent temperament. The Council of Nicaea, which opened in the early summer of 325 with an address by the Emperor, had already been preceded by a letter to the chief protagonist, Arius of Alexandria, in which Constantine stated his opinion that the dispute was fostered only by excessive leisure and academic contention, that the point at issue was trivial and could be resolved without difficulty. His optimism was not justified: neither this letter nor the Council of Nicaea itself nor the second letter, in which Constantine urged acceptance of its conclusions, was adequate to solve a dispute in which the participants were as intransigent as the theological issues were subtle. Indeed, for more than 40 years after the death of Constantine, Arianism was actually the official orthodoxy of the Eastern Empire.

The Council of Nicaea coincided almost exactly with the celebrations of the 20th anniversary of the reign of Constantine, at which, returning the compliment paid by the Emperor's attendance at their council, the bishops were honoured participants. But Constantine's visit to the West in 326, to repeat the celebrations at Rome, brought the greatest political crisis of the reign. During his absence from the East, and for reasons that remain obscure, Constantine had his eldest son, the deputy emperor Crispus, and his own wife Fausta, Crispus' stepmother, slain. Nor was the visit to Rome a success. Constantine's refusal to take part in a pagan procession offended the Romans; and when he left after a short visit, it was never to return.

Final years. These events set the course of the last phase of the reign of Constantine. After his defeat of Licinius he had renamed Byzantium as Constantinople: immediately upon his return from the West he began to rebuild the city on a greatly enlarged pattern, as his permanent capital and the "second Rome." The dedication of Constantinople (May 330) confirmed the divorce, which had been in the making for more than a century, between the emperors and Rome. Rome had long been unsuited to the strategic needs of the empire: it was now to be left in splendid isolation, as an enormously wealthy and prestigious city—still the emotional focus of the empire—but of limited political importance.

Founding of Constantinople

It was perhaps in some sense to atone for the family catastrophe of 326 that Constantine's mother, Helena, embarked on a pilgrimage to the Holy Land. Her journey was attended by almsgiving and pious works and was distinguished by her church foundations at Jerusalem and at Bethlehem. By the initiative of Eutropia, Constantine's mother-in-law, a church was also built at Mamre, where, according to an interpretation of Genesis shared by Constantine and Eusebius, Christ had first shown himself to men in God's appearance to Abraham; but the most famous of these foundations followed the sensational discovery of the Holy Sepulchre at Jerusalem. The discovery was taken up with enthusiasm by Constantine, who instigated the building of a great new basilica at the spot, offering unlimited help with labour and materials and suggestions as to design and decoration.

Constantine's interest in church building was expressed also at Constantinople, particularly in churches of the Holy Wisdom (the original Hagia Sophia) and of the Apostles. At Rome, the great church of St. Peter was begun in the later 320s and lavishly endowed by Constantine with plate and property. Meanwhile, churches at Trier, Aquileia, Cirta in Numidia, Nicomedia, Antioch, Gaza, Alexandria, and elsewhere owed their development, directly or indirectly, to Constantine's interest.

The Emperor was an earnest student of his religion. Even before the defeat of Licinius he had summoned to Trier the theologian and polemicist Lactantius, to be the tutor of Crispus. In later years, he commissioned new copies of the Bible for the growing congregations at Constantinople. He composed a special prayer for his troops and went on campaigns with a mobile chapel in a tent. He issued numerous laws relating to Christian practice and susceptibilities: for instance, abolishing the penalty of crucifixion and the practice of branding certain criminals; enjoining the observance of Sunday and saints' days; and extending privileges to the clergy while suppressing at least some offensive pagan practices.

Constantine had hoped to be baptized in the Jordan River, but perhaps because of the lack of opportunity to do so—together possibly with the reflection that his office necessarily involved responsibility for actions hardly compatible with the baptized state—he delayed the ceremony until the end of his life. It was while preparing for a campaign against Persia that he fell ill at Helenopolis. When treatment failed, he made to return to Constantinople but was forced to take to his bed near Nicomedia. There, Constantine received baptism, putting off the imperial purple for the white robes of a neophyte; and he died on May 22, 337. He was buried at Constantinople in his Church of the Apostles, whose memorials, six on each side, flanked his tomb. Yet this was less an expression of religious megalomania than of Constantine's literal conviction that he was the successor of the evangelists, having devoted his life and office to the spreading of Christianity.

Death

Assessment. The reign of Constantine must be interpreted against the background of his personal commitment to Christianity. His public actions and policies, however, were not entirely without ambiguity. Roman opinion ex-

pected of its emperors not innovation but the preservation of traditional ways; Roman propaganda and political communication were conditioned, by statement, allusion, and symbol, to express these expectations. It is significant, for instance, not that the pagan gods and their legends survived for a few years on Constantine's coinage but that they disappeared so quickly: the last of them, the relatively inoffensive "Unconquered Sun," was eliminated just over a decade after the defeat of Maxentius.

Some of the ambiguities in Constantine's public policies were therefore exacted by the respect due to established practice and by the difficulties of expressing, as well as of making, total changes suddenly. The suppression of paganism, by law and by the sporadic destruction of pagan shrines, is balanced by particular acts of deference. A town in Asia Minor mentioned the unanimous Christianity of its inhabitants in support of a petition to the Emperor; while, on the other hand, one in Italy was allowed to hold a local festival incorporating gladiatorial games and to found a shrine of the imperial dynasty—although direct religious observance there was firmly forbidden. In an early law of Constantine, priests and public soothsayers of Rome were prohibited entry to private houses; but another law, of 320 or 321, calls for their recital of prayer "in the manner of ancient observance" if the imperial palace or any other public building were struck by lightning. Traditional country magic was tolerated by Constantine. Classical culture and education, which were intimately linked with paganism, continued to enjoy enormous prestige and influence; provincial priesthoods, which were as intimately linked with civic life, long survived the reign of Constantine. Constantinople itself was predominantly a Christian city, its dedication celebrated by Christian services; yet its foundation was also attended by a well-known pagan seer, Sopatros.

An objective assessment of Constantine's secular achievements is not easy—partly because of the predominantly religious significance with which the Emperor himself invested his reign, partly because the restlessly innovatory character that dissenting contemporaries saw in his religious policy was also applied by them to the interpretation of his secular achievement. Some of Constantine's contributions can, in fact, be argued to have been already implicit in the trends of the last half century. So may be judged the further development, taking place in his reign, of the administrative court hierarchy and an increasing reliance upon a mobile field army, to what was considered the detriment of frontier garrisons. The establishment by Constantine of a new gold coin, the solidus, which was to survive for centuries as the basic unit of Byzantine currency, could hardly have been achieved without the work of his predecessors in restoring political and military stability after the anarchy of the 3rd century. Perhaps more directly linked with Constantine's own political and dynastic policies was the emergence of regional praetorian prefectures with supreme authority over civil financial administration but with no direct control over military affairs; this they yielded to new *magistri*, or "masters," of the cavalry and infantry forces. The reduction of the prefects' powers was seen by some as excessively innovatory, but the principle of the division of military and civil power had already been established by Diocletian. A real innovation, from which Constantine could expect little popularity, was his institution of a new tax, the *collatio lustralis*. It was levied every five years upon trade and business and seems to have become genuinely oppressive.

Secular achievements

A lavish spender, Constantine was notoriously open-handed to his supporters and was accused of promoting beyond their deserts men of inferior social status. More to the point is the accusation that his generosity was only made possible by his looting of the treasures of the pagan temples as well as by his confiscations and new taxes; and there is no doubt that some of his more prominent supporters owed their success, at least partly, to their timely adoption of the Emperor's religion.

The foundation of Constantinople, an act of crucial long-term importance, was Constantine's personal achievement. Yet it, too, had been foreshadowed; Diocletian enhanced Nicomedia to an extent that was considered to challenge Rome. The city itself exemplified the "religious rapacity" of the Emperor, being filled with the artistic spoils of the Greek temples, while some of its public buildings and some of the mansions erected for Constantine's supporters soon showed signs of their hasty construction. Its Senate, created to match that of Rome, long lacked the aristocratic pedigree and prestige of its counterpart.

In military policy Constantine enjoyed unbroken success, with triumphs over the Franks, Sarmatians, and Goths to add to his victories in the civil wars; the latter, in particular, show a bold and imaginative mastery of strategy. Constantine was totally ruthless toward his political enemies, while his legislation, apart from its concessions to Christianity, is notable mainly for a brutality that became characteristic of late Roman enforcement of law. Politically, Constantine's main contribution was perhaps that, in leaving the empire to his three sons, he reestablished a dynastic succession, but it was secured only by a sequence of political murders after his death.

Above all, Constantine's achievement was perhaps greatest in social and cultural history. It was the development, after his example, of a Christianized imperial governing class that, together with his dynastic success, most firmly entrenched the privileged position of Christianity; and it was this movement of fashion, rather than the enforcement of any program of legislation, that was the basis of the Christianization of the Roman Empire. Emerging from it in the course of the 4th century were two developments that contributed fundamentally to the nature of Byzantine and Western medieval culture: the growth of a specifically Christian, biblical culture that took its place beside the traditional Classical culture of the upper classes; and the extension of new forms of religious patronage, between the secular governing classes and bishops, Christian intellectuals and holy men. Constantine left much for his successors to do, but it was his personal choice made in 312 that determined the emergence of the Roman Empire as a Christian state. It is not hard to see why Eusebius regarded Constantine's reign as the fulfillment of divine providence—nor to concede the force of Constantine's assessment of his own role as that of the 13th Apostle.

BIBLIOGRAPHY

Biographies and commentaries: Two accounts remain classic: ch. 14–18 of EDWARD GIBBON, *The History of the Decline and Fall of the Roman Empire*, edited by J.B. BURY, vol. 1 and 2 (1896), available also in many later editions; and JACOB BURCKHARDT, *The Age of Constantine the Great* (1949, reissued 1983; originally published in German, 1880). NORMAN H. BAYNES, *Constantine the Great and the Christian Church* (1930, reprinted 1975), is still a fundamental study, emphasizing the authenticity of Constantine's own writings. See also A.H.M. JONES, *Constantine and the Conversion of Europe* (1948, reissued 1978), and *The Later Roman Empire, 284–602*, 2 vol. (1964, reprinted 1986); ANDREW ALFÖLDI, *The Conversion of Constantine and Pagan Rome*, trans. from German (1948, reprinted 1969); JOSEPH VOGT, *Constantin der Grosse und sein Jahrhundert*, 2nd rev. ed. (1960); and RAMSAY MACMULLEN, *Constantine* (1969, reissued 1971). TIMOTHY D. BARNES, *Constantine and Eusebius* (1981), and *The New Empire of Diocletian and Constantine* (1982), are basic reappraisals of the political and religious background of Constantine's career. On the foundation of Constantinople, see GILBERT DAGRON, *Naissance d'une capitale: Constantinople et ses institutions de 330 á 451* (1974). On Constantine's church building, see RICHARD KRAUTHEIMER, *Early Christian and Byzantine Architecture*, 3rd ed. rev. (1981).

Sources: For Constantine's letters, see especially the modern translations of EUSEBIUS, *Church History*, Book X, and *Life of Constantine*, both in *A Select Library of Nicene and Post-Nicene Fathers of the Christian Church, Second Series*, vol. 1 (1961); and LACTANTIUS, *De Mortibus Persecutorum*, edited and translated by J.L. CREED (1984), part of the "Oxford Early Christian Texts" series. Eusebius' panegyrics of Constantine are translated and discussed in H.A. DRAKE, *In Praise of Constantine: A Historical Study and New Translation of Eusebius' Tricennial Orations* (1976). The ancient secular accounts are scanty; the fullest account, although with a hostile bias, is ZOSIMUS, *Historia nova*, available in a modern translation by RONALD T. RIDLEY, *New History* (1982). The bulk of Constantine's surviving legislation is in the *Codex Theodosianus*, in an edition translated by CLYDE PHARR, *The Theodosian Code and Novels, and the Sirmondian Constitutions* (1952, reissued 1969).

(J.F.Ma./D.M.N.)

Constitution and Constitutional Government

The general idea of a constitution and of constitutionalism originated with the ancient Greeks and especially in the systematic, theoretical, normative, and descriptive writings of Aristotle. In his *Politics, Nicomachean Ethics, Constitution of Athens,* and other works, Aristotle used the Greek word for constitution (*politeia*) in several different senses. The simplest and most neutral of these was "the arrangement of the offices in a *polis*" (state). In this purely descriptive sense of the word, every state has a constitution, no matter how badly or erratically governed it may be.

This article deals with the theories and classical conceptions of constitutions as well as the features and practice of constitutional government throughout the world. It is divided into the following sections:

THEORIES ABOUT CONSTITUTIONS

Aristotle's classification of the "forms of government" was intended as a classification of constitutions, both good and bad. Under good constitutions—monarchy, aristocracy, and the mixed kind to which Aristotle applied the same term *politeia*—one person, a few individuals, or the many rule in the interest of the whole *polis.* Under the bad constitutions—tyranny, oligarchy, and democracy—the tyrant, the rich oligarchs, or the poor *dēmos,* or people, rule in their own interest alone.

Aristotle regarded the mixed constitution as the best arrangement of offices in the *polis.* Such a *politeia* would contain monarchic, aristocratic, and democratic elements. Its citizens, after learning to obey, were to be given opportunities to participate in ruling. This was a privilege only of citizens, however, since neither noncitizens nor slaves would have been admitted by Aristotle or his contemporaries in the Greek city-states. Aristotle regarded some humans as natural slaves, a point on which later Roman philosophers, especially the Stoics and jurists, disagreed with him. Although slavery was at least as widespread in Rome as in Greece, Roman law generally recognized a basic equality among all humans. This was because, the Stoics argued, all humans are endowed by nature with a spark of reason by means of which they can perceive a universal natural law that governs all the world and can bring their behaviour into harmony with it.

Influence of Roman law

Roman law thus added to Aristotelian notions of constitutionalism the concepts of a generalized equality, a universal regularity, and a hierarchy of types of laws. Aristotle had already drawn a distinction between the constitution (*politeia*), the laws (*nomoi*), and something more ephemeral that corresponds to what could be described as day-to-day policies (*psēphismata*). The latter might be based upon the votes cast by the citizens in their assembly and might be subject to frequent changes, but *nomoi,* or laws, were meant to last longer. The Romans conceived of the all-encompassing rational law of nature as the eternal framework to which constitutions, laws, and policies should conform—the constitution of the universe.

Influence of the church. Christianity endowed this universal constitution with a clearly monarchical cast. The Christian God, it came to be argued, was the sole ruler of the universe, and his laws were to be obeyed. Christians were under an obligation to try to constitute their earthly cities on the model of the City of God.

Both the church and the secular authorities with whom the church came into conflict in the course of the Middle Ages needed clearly defined arrangements of offices, functions, and jurisdictions. Medieval constitutions, whether of church or state, were considered legitimate because they were believed to be ordained of God or tradition or both. Confirmation by officers of the Christian Church was regarded as a prerequisite of the legitimacy of secular rulers. Coronation ceremonies were incomplete without a bishop's participation. The Holy Roman emperor travelled to Rome in order to receive his crown from the pope. Oaths, including the coronation oaths of rulers, could be sworn only in the presence of the clergy because oaths constituted promises to God and invoked divine punishment for violations. Even in an imposition of a new constitutional order, novelty could always be legitimized by reference to an alleged return to a more or less fictitious "ancient constitution." It was only in Italy during the Renaissance and in England after the Reformation that the "great modern fallacy" (as the Swiss historian Jacob Burckhardt called it) was established, according to which citizens could rationally and deliberately adopt a new constitution to meet their needs.

The social contract. The theoretical foundations of modern constitutionalism were laid down in the great works on the social contract, especially those of the English philosophers Thomas Hobbes and John Locke in the 17th century and the French philosopher Jean-Jacques Rousseau in the 18th.

Impact of the Reformation

As a result of the Reformation the basis of divinely sanctioned contractual relations was broken up. The Holy Roman Empire was torn apart by the wars of the Reformation. Henry VIII made the Church of England independent of Rome. In these circumstances, it became necessary to search for a new basis of order and stability, loyalty and obedience. In their search, political theorists—and especially the Protestants among them—turned to the old biblical concept of a covenant or contract, such as the one between God and Abraham and the Israelites of the Old Testament.

In a sense, the secular theorists of the social contract almost reversed the process of choice. Instead of God choosing his people, a people through its representatives was now looked upon as choosing its governors, or its mode of governance, under God, by means of a social contract or constitution. According to modern theories of the social contract, the political unit is nevertheless established as in the biblical model by means of a promise or promises.

Thomas Hobbes's state, or "Leviathan," comes into being when its individual members renounce their powers to execute the laws of nature, each for himself, and promise to turn these powers over to the sovereign—which is created as a result of this act—and to obey thenceforth the laws made by this sovereign. These laws enjoy authority because individual members of society are in effect their co-authors. According to Locke, individuals promise to agree to accept the judgments of a common judge (the legislature) when they accede to the compact that establishes civil society. After this (in one interpretation of Locke's *Second Treatise on Civil Government*), another set

of promises is made—between the members of the civil society, on the one hand, and the government, on the other. The government promises to execute its trust faithfully, leaving to the people the right to rebel in case the government breaks the terms of the contract, or, in other words, violates the constitution. Subsequent generations accept the terms of the compact by accepting the inheritance of private property that is created and protected by the compact. Anyone who rejects the constitution must leave the territory of the political unit and go *in vacuis locis,* or "empty places"—America, in Locke's time. In his *Letters on Toleration,* Locke characteristically excluded atheists from religious toleration because they could be expected either not to take the original contractual oath or not to be bound by the divine sanctions invoked for its violation. For Rousseau, too, the willingness to subject oneself to the "general will" to which only the popular sovereign can give expression is the essential ingredient of the social contract. In taking this position, Rousseau may have been influenced by the experience of his native Geneva. The Swiss Confederation is still referred to officially, in German, as an *Eidgenossenschaft,* a term best translated as "fellowship of the oath."

Hobbes's view on sovereignty

Hobbes's main contribution to constitutionalism lies in his radical rationalism. Individuals, according to Hobbes, come together out of the state of nature, which is a state of disorder and war, because their reason tells them that they can best ensure their self-preservation by giving all power to a sovereign. The sovereign may consist of a single person, an assembly, or the whole body of citizens; but regardless of its form, all the powers of sovereignty have to be combined and concentrated in it. Hobbes held that any division of these powers destroyed the sovereign and thereby returned the members of the commonwealth to the state of nature, in which the condition of man is ". . . solitary, poore, nasty, brutish, and short." Hobbes therefore preferred the singular sovereign since he was less likely than an assembly or than the whole body of citizens to become internally or functionally divided. The individual should retain only his natural rights, which he cannot surrender into the common pool of sovereign powers. These rights include the right against self-incrimination, the right to purchase a substitute for compulsory military service, and the right to act freely in instances in which the laws are silent.

Locke attempted to provide firm assurance of the individual's natural rights, partly by assigning separate though coordinated powers to the monarch and Parliament and partly by reserving the right of revolution against a government that had become unconstitutionally oppressive. Locke did not use the word sovereignty. In this as in other respects, he remained within the English constitutional tradition, which had eschewed the concentration of all powers in a single organ of government. The closest that English constitutionalists came to identifying the centre of sovereign power was in the phrase, used frequently from the 16th century onward, the king (or queen) in Parliament.

Rousseau's theory of the general will

Whereas Hobbes created his unitary sovereign through the mechanism of individual and unilateral promises and whereas Locke prevented excessive concentration of power by requiring the cooperation of different organs of government for the accomplishment of different purposes, Rousseau merged all individual citizens into an all-powerful sovereign whose main purpose was the expression of the general will. By definition. the general will can never be wrong; for when something contrary to the general interest is expressed, it is defined as the mere "will of all" and cannot have emanated from the sovereign. In order to guarantee the legitimacy of government and laws, Rousseau would have enforced universal participation in order to "force men to be free," as he paradoxically phrased it. In common with Hobbes and Locke, Rousseau required the assent of all to the original social contract. He required smaller majorities for the adoption of laws of lesser importance than the constitution itself. His main concern was to provide for legitimacy through universal participation in legislation, whereas Locke and Hobbes were more concerned to provide constitutional stability through consent. As a result, Rousseau's thought appears to be more democratic than that of his English predecessors. He has even been accused of laying the philosophical foundations of "totalitarian democracy," for the state he describes in *The Social Contract* would be subject, at the dictates of its universal and unanimous sovereign, to sudden changes, or even transformations, of its constitution.

Influence of social contract theory

In the political thought of Hobbes, Locke, and Rousseau may be found theoretical consideration of the practical issues that were to confront the authors of the American and French constitutions. The influence of theories of the social contract, especially as they relate to the issues of natural rights and the proper functions of government, pervades the constitution making of the revolutionary era that began with the U.S. War of Independence and is indeed enshrined in the great political manifestos of the time, the American Declaration of Independence and Bill of Rights, and the French Declaration of the Rights of Man and the Citizen.

The constitutional experience of these two countries, and, of course, of England, had great influence on liberal thought in Europe and other parts of the world during the 19th century and found expression in the constitutions that were demanded of the European monarchies. The extent to which the ideal of constitutional democracy has become entwined with the practice of constitutional government will be apparent from the examination in the following section of the main features of constitutional government.

FEATURES OF CONSTITUTIONAL GOVERNMENT

Virtually all contemporary governments have constitutions, but possession and publication of a constitution does not make a government constitutional. Constitutional government is in fact comprised of the following elements.

Procedural stability. Certain fundamental procedures must not be subject to frequent or arbitrary change. Citizens must know the basic rules according to which politics are conducted. Stable procedures of government provide citizens with adequate knowledge of the probable consequences of their actions. By contrast, under many nonconstitutional regimes, such as Hitler's in Germany and Stalin's in the Soviet Union, individuals, including high government officials, never knew from one day to the next whether the whim of the dictator's will would not turn today's hero into tomorrow's public enemy.

Accountability. Under constitutional government, those who govern are regularly accountable to at least a portion of the governed. In a constitutional democracy, this accountability is owed to the electorate by all persons in government. Accountability can be enforced through a great variety of regular procedures, including elections, systems of promotion and discipline, fiscal accounting, recall, and referendum. In constitutional democracies, the accountability of government officials *to* the citizenry makes possible the citizens' responsibility *for* the acts of government. The most obvious example of this two-directional flow of responsibility and accountability is the electoral process. A member of the legislature or the head of government is elected by adult citizens and is thereby invested with authority and power in order that he may try to achieve those goals to which he committed himself in his program. At the end of his term of office, the electorate has the opportunity to judge his performance and to reelect him or dismiss him from office. The official has thus rendered his account and has been held accountable.

Representation. Those in office must conduct themselves as the representatives of their constituents. To represent means to be present on behalf of someone else who is absent. Elections, of course, are not the only means of securing representation or of ensuring the representativeness of a government. Hereditary medieval kings considered themselves, and were generally considered by their subjects, to be representatives of their societies. Of the social contract theorists only Rousseau denied the feasibility of representation for purposes of legislation. The elected status of officeholders is sometimes considered no guarantee that they will be "existentially representative" of their constituents, unless they share with the latter certain

other vital characteristics such as race, religion, sex, or age. The problems of representation are in fact more closely related to democratic than to constitutionalist criteria of government: a regime that would be considered quite unrepresentative by modern standards could still be regarded as constitutional so long as it provided procedural stability and the accountability of officeholders to some but not all of the governed and so long as the governors were representative of the best or the most important elements in the body politic.

Constitutionalism

Division of power. Constitutional government requires a division of power among several organs of the body politic. Preconstitutionalist governments, such as the absolute monarchies of Europe in the 18th century, frequently concentrated all power in the hands of a single person. The same has been true in modern dictatorships such as Hitler's in Germany. Constitutionalism, on the other hand, by dividing power—between, for example, local and central government and between the legislature, executive, and judiciary—ensures the presence of restraints and "checks and balances" in the political system. Citizens are thus able to influence policy by resort to any of several branches of government.

Openness and disclosure. Democracy rests upon popular participation in government, constitutionalism upon disclosure of and openness about the affairs of government. In this sense, constitutionalism is a prerequisite of successful democracy, since the people cannot participate rationally in government unless they are adequately informed of its workings. Originally, because they were concerned with secrets of state, bureaucracies surrounded their activities with a veil of secrecy. The ruler himself always retained full access to administrative secrets and often to the private affairs of his subjects, into which bureaucrats such as tax collectors and the police could legally pry. But when both administrators and rulers were subjected to constitutional restraints, it became necessary that they disclose the content of their official activities to the public to which they owed accountability. This explains the provision contained in most constitutions obliging the legislature to publish a record of its debates.

Constitutionality. Written constitutions normally provide the standard by which the legitimacy of governmental actions is judged. In the United States, the practice of the judicial review of congressional legislation for its constitutionality—that is, for its conformity with the U.S. Constitution—though not explicitly provided for by the Constitution, developed in the early years of the republic. More recently, other written constitutions, including the Basic Law of the Federal Republic of Germany and Italy's republican constitution, provided explicitly for judicial review of the constitutionality of parliamentary legislation. This does not necessarily mean that a constitution is regarded as being prior and superior to all law. Although several European countries, including France and Italy, adopted new constitutions after World War II, they kept in force their codes of civil law, which had been legislated in the 19th century; and the U.S. Constitution guarantees citizens certain substantive and procedural rights to which they deemed themselves entitled as subjects of the British crown under the ancient English common law. Despite the greater antiquity of law codes, however, portions of them have been revised from time to time in order to eliminate conflicts between the law and certain constitutional norms that are regarded as superior. Parts of German family law and of the criminal code, for example, were revised in order to bring them into conformity with the constitutional provisions regarding the equality of persons irrespective of sex and with the individual's constitutionally guaranteed right to the free development of his personality.

Constitutional interpretation

Conflicting interests or parties are, of course, likely to place different interpretations on particular provisions of a constitution, and means, therefore, have to be provided for the resolution of such conflicts. The constitution itself may establish an institution, the task of which is to interpret and clarify the terms of that constitution. In the American system, the Supreme Court is generally regarded as the authoritative interpreter of the Constitution. But the Supreme Court cannot be regarded as the "final" interpreter of the meaning of the Constitution for a number of reasons. The court can always reverse itself, as it has done before. The president can gradually change the interpretative outlook of the court through the nomination of new justices, and the Congress can exert a more negative influence by refusing to confirm presidential nominations of justices.

Provision was made in the constitution of the Fifth French Republic for the interpretation of certain constitutional matters by a Constitutional Council. Soon after the French electorate, in a referendum in 1958, had voted to accept the Constitution, a controversy erupted in France over the question of whether the president of the republic could submit to popular referendum issues not involving constitutional amendments but on which parliament had taken a position at odds with the president's. The Constitution itself seemed to provide that the Constitutional Council could rule definitively on this question, but Pres. Charles de Gaulle chose to ignore its ruling, which was unfavourable to himself. As a result, the Constitutional Council lost authority as the final interpreter of the meaning of the Constitution of the Fifth Republic.

It may thus be seen that because of the inherent difficulties in assessing the intentions of the authors of a constitution and because of the possibility that the executive or legislative branch of government may be able to ignore, override, or influence its findings, it is difficult to ensure constitutional government merely by setting up an institution whose purpose is constitutional interpretation.

Changing unwritten and written constitutions

Constitutional change. Written constitutions are not only likely to give rise to greater problems of interpretation than unwritten ones, but they are also harder to change. Unwritten constitutions tend to change gradually, continually, and often imperceptibly, in response to changing needs. But when a constitution lays down exact procedures for the election of the president, for relations between the executive and legislative branches, or for defining whether a particular governmental function is to be performed by the federal government or a member state, then the only constitutional way to change these procedures is by means of the procedure provided by the constitution itself for its own amendment. Any attempt to effect change by means of judicial review or interpretation is unconstitutional, unless, of course, the constitution provides that a body (such as the U.S. Supreme Court) may change, rather than interpret, the constitution.

Many constitutional documents make no clear distinction between that which is to be regarded as constitutional, fundamental, and organic, on the one hand, and that which is merely legislative, circumstantial, and more or less transitory, on the other. The constitution of the German Weimar Republic could be amended by as little as four-ninths of the membership of the Reichstag, without any requirement for subsequent ratification by the states, by constitutional conventions, or by referendum. Although Hitler never explicitly abrogated the Weimar Constitution, he was able to replace the procedural and institutional stability that it had sought to establish with a condition of almost total procedural and institutional flux.

A similar situation prevailed in the Soviet Union under the rule of Stalin. But Stalin took great trouble and some pride in having a constitution bearing his name adopted in 1936. The Stalin constitution continued, together with the Rules of the Communist Party of the Soviet Union, to serve as the formal framework of government until the ratification of a new, though rather similar, constitution in 1977. The procedures established by these documents, however, were not able to provide Soviet citizens and politicians with reliable knowledge of the rules of the political process from one year to the next or with guidance as to which institutions and practices they were to consider fundamental or virtually sacrosanct and which they could safely criticize. As a result, changes in the personnel and policies of the Soviet Union and of similar Communist regimes were rarely brought about smoothly and frequently required the use of violence.

Constitutional stability. If one distinguishes between stability and stagnation on the one hand and between flexibility and flux on the other, then one can consider

Characteristics of stable constitutions

those constitutional systems most successful that combine procedural stability with substantive flexibility—that is, that preserve the same general rules of political procedure from one generation to the next while at the same time facilitating adaptation to changing circumstances. By reference to such criteria, those written constitutions have achieved the greatest success that are comparatively short; that confine themselves in the main to matters of procedure (including their own amendment) rather than matters of substance; that, to the extent that they contain substantive provisions at all, keep these rather vague and generalized; and that contain procedures that are congruent with popular political experience and know-how. These general characteristics appear to be more important in making for stability than such particular arrangements as the relations between various organs and levels of government or the powers, functions, and terms of tenure of different officers of state.

There is little evidence to support the thesis that a high level of citizen participation necessarily contributes to the stability of constitutional government. On the contrary, the English political economist Walter Bagehot, who in 1867 wrote a classic analysis of the English constitution (*The English Constitution*), stressed the "deferential" character of the English people, who were quite happy to leave government in the hands of the governing class.

Much more important than formal citizen behaviour, such as electoral participation, are informal attitudes and practices and the extent to which they are congruent with the formal prescriptions and proscriptions of the constitution itself. Constitutional government cannot survive effectively in situations in which the constitution prescribes a pattern of behaviour or of conducting affairs that is alien to the customs and way of thinking of the people. When, as happened in many developing countries in the decades after World War II, a new and alien kind of constitutional democracy is imposed or adopted, a gap may soon develop between constitutionally prescribed and actual governmental practice. This in turn renders the government susceptible to attack by opposition groups. Such attack is especially easy to mount in situations in which a constitution has a heavy and detailed substantive content, when, for example, it guarantees the right to gainful employment or the right to a university education for all qualified candidates. In the event of the government being unable to fulfill its commitment, the opposition is able to call the constitution a mere scrap of paper and to demand its improvement or even its complete replacement. Such tactics often have succeeded, but they ignore the dual strategic function of the constitution. It is meant not only to arrange the offices of the state, in Aristotle's sense, but also to state the goals toward which the authors and ratifiers of the constitution want their community to move.

THE PRACTICE OF CONSTITUTIONAL GOVERNMENT

Great Britain. It is accepted constitutional theory that Parliament (the House of Commons and the House of Lords acting with the assent of the monarch) can do anything it wants to, including abolish itself. The interesting aspect of British government is that, despite the absence of restraints such as judicial review, acts that would be considered unconstitutional in the presence of a written constitution are attempted very rarely, certainly less often than in the United States.

The English constitution and the English common law grew up together, very gradually, more as the result of the accretion of custom than through deliberate, rational legislation by some "sovereign" lawgiver. Parliament grew out of the Curia Regis, the King's Council, in which the monarch originally consulted with the great magnates of the realm and later with commoners who represented the boroughs and the shires. Parliament was, and is, a place in which to debate specific issues of disagreement between, initially, the crown, on the one hand, and the Lords and Commons, on the other. The conflicts were settled in Parliament so that its original main function was that of a court—it was in fact known as "the High Court of Parliament" as late as the 16th century.

The locus of power in the English constitution shifted gradually as a result of changes in the groups whose consent the government required in order to be effective. In feudal times, the consent of the great landowning noblemen was needed. Later, the cooperation of commoners willing to grant revenue to the crown—that is, to pay taxes—was sought. The crown itself, meanwhile, was increasingly institutionalized, and the distinction was drawn ever more clearly between the private and public capacities of the king. During the course of the 18th century, effective government passed more and more into the hands of the king's first minister and his cabinet, all of them members of one of the two houses of Parliament. Before this development, the king's ministers depended upon their royal master's confidence to continue in office. Henceforward they depended upon the confidence of the House of Lords and especially the House of Commons, which had to vote the money without which the king's government could not be carried on. In this way the parlay that was originally between the monarch and the houses of Parliament was now struck between the ministry and its supporters, on the one hand, and opposing members of Parliament, on the other. Parliamentary factions were slowly consolidated into parliamentary parties, and these parties reached out for support into the population at large by means of the franchise, which was repeatedly enlarged in the course of the 19th century and eventually extended to women and then to 18-year-olds in the 20th.

Parliamentary opposition

When a prime minister loses a vote of confidence in the House of Commons, he can either resign to let the leader of the Opposition form a new government or ask the monarch to dissolve Parliament and call for new elections. As a result of the strong party discipline that developed in the 20th century, prime ministers generally do not lose votes of confidence any more, and they call for new elections at the politically most favourable moment. According to an act of Parliament, elections must be held at least every five years—but another act of Parliament can change or suspend this apparently "constitutional" provision, as was done during World War II, when the life of the incumbent House of Commons was extended until the defeat of Germany. Similarly, relations between, and the relative powers of, the House of Lords and the House of Commons have been repeatedly redefined to the disadvantage of the House of Lords by acts of Parliament, to such an extent that the Lords retain only a weak suspensory veto. All such fundamental constitutional changes have occurred either informally and without any kind of legislation at all or as a result of the same legislative procedures employed to pass any other ordinary circumstantial bill.

United States. The U.S. Constitution is not only replete with phrases taken from the British constitutional vocabulary, but in several respects, it also represents a codification of its authors' understanding of the English constitution, to which they added ingenious federalist inventions and the formal amending procedure itself. Despite the availability of this procedure, however, many if not most of the fundamental changes in American constitutional practice have not been effected by formal amendments. The Constitution still does not mention political parties or the president's cabinet. Nor was the Constitution changed in order to bring about or to sanction the fundamentally altered relations between the executive and the Congress, between the Senate and the House, and between the judiciary, the legislature, and the executive.

The presence of a constitutional document, however, has made American politics more consciously "constitutionalist," at least in the sense that politicians in the United States take more frequent recourse than their British counterparts to legalistic argumentation and to actual constitutional litigation. The United States, moreover, is denied the kind of flexibility illustrated by the postponement of British parliamentary elections during World War II since the Constitution explicitly provides the dates for congressional and presidential elections. It is one of the remarkable facts of American constitutional history that the constitutional timetable for elections has always been observed, even during external war and the Civil War of the 19th century.

Europe. France, Germany, and Italy, as well as most non-European countries influenced by continental concepts of constitutionalism, have no record of unbroken constitutional fidelity similar to that found in Britain and the U.S. Because of the highly substantive and ideological content of most French constitutions, the best way to change them has been to replace them altogether with a new, ideologically different document. Only the constitution of the Third Republic (established in 1870) was exceptional in this respect, since it consisted of very short, highly procedural organic laws, which served France well for 70 years, until the German invasion of 1940.

Constitutional government in France

The main political problem attributed to the constitution of the Third Republic was the instability of cabinets. The negative majorities that voted "no confidence" in a cabinet usually could not stay together for the positive purpose of confirming a new cabinet. The constitution of the Fourth Republic (1946–58) made the overthrow of governments by the National Assembly more difficult. In fact, however, the life of the average cabinet in the Fourth Republic was even shorter than in the Third, and French government became virtually paralyzed when it had to deal with the problems raised by the Algerian independence movement. To avert a military takeover, General de Gaulle was given wide discretion in 1958 in the formulation of a new constitution, which was overwhelmingly accepted in a referendum. The constitution of the Fifth French Republic gives the president of the Republic the power to dissolve Parliament and the means of circumventing a hostile National Assembly through the referendum. Since 1958, French cabinets have been very stable indeed, and the constitution proved resilient during the "revolution of 1968."

Germany, which was unified as a national state only in 1871, established its first democratic constitution in 1919, after its defeat in World War I. Although some of the greatest German jurists and social scientists of the time participated in writing the Weimar Constitution, it has been adjudged a failure. Political parties became highly fragmented, a phenomenon that was explained partly by an extremely democratic electoral law (not a part of the constitution) providing for proportional representation. Some of the parties of the right, such as Hitler's Nazis, and of the left, such as the Communists, were opposed to the constitutional order and used violence in their efforts to overthrow the Republic. To deal with these threats, the President used his constitutional emergency powers under which he could suspend civil rights in member states of the federal system. Several chancellors (the German equivalent of a prime minister) stayed in office after the President had dissolved a Parliament in which the chancellor lacked a supporting majority. They continued to govern with the help of presidential emergency powers and by legislating on the basis of powers previously delegated to them by Parliament.

Failure of the Weimar Constitution

When a new constitution was drafted for the Western zones of occupation after World War II, every effort was made to correct those constitutional errors to which the failure of the Weimar Republic was attributed. Under the Basic Law of the Federal Republic of Germany, Parliament cannot delegate its legislative function to the chancellor, and civil rights cannot be suspended without continuous parliamentary surveillance. The president has been turned into a figurehead on the model of the French presidents of the Third and Fourth Republics, and Parliament cannot overthrow a chancellor and his cabinet unless it first elects a successor with the vote of a majority of its members. Negative majorities cannot paralyze government unless they can agree on alternative policies and personnel. The extreme form of proportional representation used before Hitler came to power was replaced by a mixed electoral system under which half the members of the Bundestag (the lower house of the legislature) are elected from party lists by proportional representation, while the other half are elected in single member constituencies. In order to benefit from proportional representation, a party must obtain at least 5 percent of the votes cast. As a result, the number of parties steadily contracted during the first two decades of the Federal Republic and extremist parties were kept out of Parliament. Cabinets have been very stable, and the provision for the "constructive vote of no confidence" was invoked for the first time only in 1982.

Latin America, Africa, and Asia. The experience of constitutional government in continental Europe exerted great influence on the newly independent former colonies of Europe in the Middle East, Asia, and Africa. In the early years of their independence from Spain, most Latin-American countries adopted constitutions similar to that of the United States. But since they lacked the background that produced the American Constitution, including English common law, most of their efforts at constitutional engineering were unsuccessful.

In Asia and Africa and in the Caribbean, many former colonies of Great Britain, such as India, Nigeria, Zambia, and Jamaica, have been comparatively more successful in the operation of constitutional government than former colonies of the continental European countries (*e.g.,* Indonesia, Congo, and Haiti). The British usually left a modified and simplified version of their own constitution upon granting independence to their former subjects, some of whom they had previously trained in the complicated operating procedures of the British constitution. British parliamentary procedure proved sufficiently adaptable to remain in use for some time after the departure of the British themselves. France's former colonies in Africa, because they achieved independence after the founding of the Fifth Republic, modeled their new constitutions upon General de Gaulle's, partly because this enhanced the power of the leaders under whom independence had been achieved.

The success of British and French models

BIBLIOGRAPHY. Current texts of more than 150 national constitutions are available in English translation in ALBERT P. BLAUSTEIN and GISBERT H. FLANZ (eds.), *Constitutions of the Countries of the World,* 20 vol. (1971–), issued in looseleaf format and updated frequently.

An intellectual overview is provided by A.V. DICEY, *Introduction to the Study of the Law of the Constitution,* 10th ed. (1959, reissued 1985). WILLIAM S. LIVINGSTON, *Federalism and Constitutional Change* (1956, reprinted 1974), stands as the best study of constitutional change. Additional works include EDWARD MCWHINNEY, *Constitution-Making* (1981); and JON ELSTER and RUNE SLAGSTAD (eds.), *Constitutionalism and Democracy* (1988).

WALTER BAGEHOT, *The English Constitution* (1867, reissued 1993), remains a classic exposition. The best history of the origins of English constitutionalism is CHARLES HOWARD MCILWAIN, *The High Court of Parliament and Its Supremacy* (1910, reprinted 1979).

ALEXANDER HAMILTON, JAMES MADISON, and JOHN JAY, *The Federalist* (1788), has been reissued many times and is indispensable for understanding the origins of American constitutionalism. The basis of American constitutionalism is ably traced in DONALD S. LUTZ, *The Origins of American Constitutionalism* (1988); and DAVID A.J. RICHARDS, *Foundations of American Constitutionalism* (1989). A discussion of the impact of the American constitution upon the political process is SARAH BAUMGARTNER THUROW (ed.), *Constitutionalism in America,* vol. 3, *Constitutionalism in Perspective* (1988).

Constitutionalism in Europe is treated by SAMUEL H. BEER and ADAM B. ULAM (eds.), *Patterns of Government: The Major Political Systems of Europe,* 3rd ed. (1973); STANLEY HOFFMANN *et al., Decline or Renewal?: France Since the 1930s* (1974); RALF DAHRENDORF, *Society and Democracy in Germany* (1967, reprinted 1992; originally published in German, 1965); ARNOLD J. HEIDENHEIMER and DONALD P. KOMMERS, *The Governments of Germany,* 4th ed. (1975); and VERNON BOGDANOR (ed.), *Constitutions in Democratic Politics* (1988), on the European Community. The impact of American constitutionalism upon other nations is the topic of GEORGE ATHAN BILLIAS (ed.), *American Constitutionalism Abroad* (1990).

Studies of constitutional development include B.O. NWABUEZE, *Constitutionalism in the Emergent States* (1973); LAWRENCE WARD BEER (ed.), *Constitutionalism in Asia* (1979); and WILLIAM B. SIMONS (ed.), *The Constitutions of the Communist World* (1980), still of historical interest. The potential role of constitutions in resolving societal conflict is considered in ALBERT P. BLAUSTEIN and DANA BLAUSTEIN EPSTEIN, *Resolving Language Conflicts: A Study of the World's Constitutions* (1986). DOUGLAS GREENBERG *et al.* (eds.), *Constitutionalism and Democracy* (1993), offers an excellent compilation of studies of constitutionalism after the recent transitions to democracy.

(H.J.Sp./Ed.)

Constitutional Law

Constitutional law is the body of rules, doctrines, and practices that govern the operation of political communities. In modern times by far the most important political community has been the national state. Modern constitutional law is the offspring of nationalism as well as of the idea that the state must protect certain fundamental rights of the individual. As national states have multiplied in number, so have constitutions and with them the body of constitutional law. But constitutional law originates today sometimes from non-national sources too, while the protection of individual rights has become the concern also of supranational institutions.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 552.

This article is divided into the following sections:

Constitutions and constitutional law

THE NATURE OF CONSTITUTIONAL LAW

In the broadest sense a constitution is a body of rules governing the affairs of an organized group. A parliament, a church congregation, a social club, or a trade union may operate under the terms of a formal written document labeled constitution. This does not mean that all of the rules of the organization are in the constitution, for usually there are many other rules such as bylaws and customs. Invariably, by definition, the rules spelled out in the constitution are considered to be basic, in the sense that, until they are modified according to an appropriate procedure, all other rules must conform with them. Thus the presiding officer of a club is obliged to rule that a proposal is out of order if it is contrary to a provision of its constitution. Implicit in the concept of a constitution is that of a higher law that takes precedence.

Every political community, and thus every national state, has a constitution, at least in the sense that it operates its important institutions according to some fundamental body of rules. In this sense of the term the only conceivable alternative to a constitution is a condition of anarchy. Constitutions may be written or unwritten; they may be complex or simple; they may provide for vastly different patterns of governance. Even if the only rule that matters is the whim of an absolute dictator, that may be said to be the constitution. (G.B./D.Fe.)

The constitution of a political community is therefore composed, in the first place, of the principles determining the agencies to which the task of governing the community is entrusted and their respective powers. In absolute monarchies, such as the Oriental kingdoms and the Roman Empire in antiquity and the French monarchy between the 16th and 18th centuries, all sovereign powers were concentrated in one person, the king or emperor, who exercised them directly or through subordinate agencies that had to act according to his instructions. In ancient republics, such as Athens and Rome, the constitution provided, as do the constitutions of most modern states, for a distribution of powers among distinct agencies. But whether it concentrates or distributes these powers, a constitution always contains at least the rules that define the structures and operations of the government that runs the community.

Necessary and contingent elements of constitutions

The constitution of a political community may contain more, however, than the definition of the authorities endowed with powers to command. It may also include principles that delimit those powers in order to secure against them fundamental rights of persons or groups. The idea that political sovereignty is not unlimited stems from an old tradition in Western philosophy. Well before the advent of Christianity, Greek philosophers thought that positive law—*i.e.*, the law actually enforced in a community—in order to be just must reflect the principles of a superior, ideal law: natural law. Similar conceptions were propagated in Rome by Cicero and by the Stoics. Later the Church Fathers and the Scholastics held that positive law was binding only if it did not conflict with the precepts of divine law. These considerations did not remain abstract speculations of philosophers and theologians; to a measure, they found reception in fundamental rules of positive legal systems. In Europe, for example, the authority of political rulers throughout the Middle Ages did not extend to religious matters, which were strictly reserved to the jurisdiction of the church. The powers of political rulers, moreover, were limited by the rights of at least some classes of subjects. Quarrels and fights over the extent of such rights were not infrequent; and they were sometimes settled through solemn, legal "pacts" among the contenders, the prominent example being Magna Carta (1215). In the modern age, even the powers of an absolute monarch such as the king of France were not truly absolute: acting alone, he could not alter the fundamental laws of the kingdom or disestablish the Roman Catholic Church.

Against this background of already existing legal limitations on the powers of governments, a decisive turn in the history of Western constitutional law occurred when a theory of natural law based on the "inalienable rights" of the individual was developed. John Locke (1632–1704) was the first outstanding champion of the theory. He was followed by others, and in the 18th century the doctrine of the rights of the individual became the banner of the Enlightenment. The theory assumed that there are certain rights belonging to every single human being (religious freedom, freedom of speech, freedom to acquire and possess property, freedom not to be punished on the basis of retroactive laws and of unfair criminal procedures, and so on), which governments cannot "take away" because they were not "created" by governments. The theory further assumed that governments must be organized in such a way as to afford an effective protection of the rights of the individual. For that purpose it was thought that, as a minimal prerequisite, governmental functions must be divided into legislative, executive, and judicial; that executive action must comply with the rules laid down by the legislature; and that remedies, administered by an independent judiciary, must be available against illegal executive action.

The theory of the rights of the individual was a potent factor in reshaping the constitutions of Western states in the 17th, 18th, and 19th centuries. The first step was made by England at the time of the Glorious Revolution (1688). All of these principles concerning the distinction of governmental functions and their appropriate relations were incorporated in constitutional law. England also soon

Modern constitutional law

changed some of its laws so as to give more adequate legal force to the newly discovered individual freedoms. It was in the United States, however, that the theory scored its most complete success. Once the English colonies became independent states (1776), they faced the problem of giving themselves a fresh political organization. They seized the opportunity to spell out in special legal documents, which could be amended only through a special procedure, all the main principles providing for the distribution of governmental functions among distinct state agencies as required by the theory, as well as the main principles concerning the rights of the individual the theory wanted to be respected by all state powers. The federal Constitution (1788) and its Bill of Rights (Amendments I–X, 1791) did the same, shortly thereafter, at the national level. By giving through this device a formal, higher status to rules defining the essential organization of government, as well as the essential limitations of its legislative and executive powers, U.S. constitutionalism put in full evidence the character that belongs, in essence, to all constitutional law: the fact of its being "basic" with respect to all other laws of the legal system. This also made it possible to set up institutional controls over the conformity even of legislation with the group of rules considered, within the system, to be of supreme importance.

The American idea of stating in an orderly, comprehensive document the essentials of the rules that must guide the operations of government became popular very quickly. Since the end of the 18th century scores of states, in Europe and elsewhere, have followed the United States' example. Today, almost all states have constitutional documents describing the fundamental organs of the state, the ways they should operate, and, usually, the rights they must respect and even sometimes the goals they ought to pursue. To be sure, not all of these documents are inspired by the individualistic ideas that permeate modern Western constitutional law. The constitutions of Communist countries, for instance, organize state powers and their relations in ways that differ from Western thought and subordinate individual freedoms to the goal of achieving a classless society. Yet, notwithstanding great differences among themselves, the constitutional charters of contemporary states are all similar at least in one respect: they are meant to express the core of the constitutional law governing their respective countries. (G.B.)

CHARACTERISTICS OF CONSTITUTIONS

Every state has a constitution, since every state functions on the basis of certain rules and principles. It has often been asserted that the United States has a written constitution but that the constitution of Great Britain is unwritten. This is true, but only in the sense that in the United States there is a formal document called the Constitution, whereas there is no such document in Great Britain. In fact, however, many parts of the British constitution exist in written form, whereas important aspects of the American constitution are wholly unwritten. The British constitution includes the Bill of Rights (1689), the Act of Settlement (1700–01), the Parliament Act of 1911, the successive Representation of the People acts (which extended the suffrage), the statutes dealing with the structure of the courts, the various local government acts, and many others. These are not ordinary statutes, even though they were adopted in the ordinary legislative way, and they are not codified within the structure of a single orderly document. On the other hand, such institutions in the United States as the presidential cabinet and the system of political parties, though not even mentioned in the written constitution, are most certainly of constitutional significance. (D.Fe.)

Written and unwritten constitutions

Written constitutions, indeed, can never exhaust the whole constitutional law of a state. They are always supplemented, to varying degrees, by statutes, judicial doctrines interpreting the constitution, intergovernmental practices, and nongovernmental institutions (such as political parties) and their practices. Without these supplementary elements the overall constitutional framework of the political community would not be what it is.

Whether "long" or "short," written constitutions can concern themselves exclusively or prevalently with the "organization" of government or deal extensively also with the rights of the people and with the goals of governmental action. The U.S. Constitution is a model of brevity (*c.* 7,000 words). Just a little longer are most of the Western countries' constitutions. On the other hand, the constitutions of India and Yugoslavia extend to hundreds of pages. Merely "organizational" constitutions (*i.e.*, documents containing no guarantees for rights) have become very rare.

Written constitutions are said to be "normative" when their binding principles are more or less all observed in the actual operations of the political system. This applies to the constitutions of the United States, of Canada, and of the western European countries. Other constitutions are said to be "nominal," because they are largely or in substantial parts disregarded and do not provide insight into the real functioning of the system. This is often the case with constitutions of rapidly developing countries and of countries ruled by a one-man or a one-party dictatorship.

Constitutions, written or unwritten, must be distinguished according to whether they are "rigid" or "flexible." Rigid are those constitutions at least some part of which cannot be modified in the ordinary legislative way. Flexible are those whose rules can all be modified through the simple procedure by which statutes are enacted. The United States has a rigid constitution, because proposals to amend the constitutional document adopted in 1788 must have a two-thirds majority vote in each house of Congress or be made by a convention called by two-thirds of the states, with subsequent ratification, in either case, by the legislatures or specially elected conventions of three-fourths of the states. Great Britain has a flexible constitution because all of its constitutional institutions and rules can be abrogated or modified by an act of Parliament.

Rigid and flexible constitutions

As almost all states have by now adopted written constitutions and these almost invariably provide for a special, exacting procedure for their amendment, the great majority of today's constitutions are rigid.

The distinction between rigid and flexible constitutions is important because only under rigid constitutions is it possible to establish institutional controls over the conformity of legislation with the principles considered indispensable for the well-being of the community. The importance of the distinction in relation to the issue of the stability and continuity of a country's constitutional law may, however, be easily exaggerated. In the United States it is difficult to activate the amending process. But in other countries with rigid constitutions, amending them is easier. In Switzerland the federal constitution of 1874 can be amended, on the initiative of 100,000 citizens or of the legislature, by a majority vote in a national referendum, with a favourable decision in the majority of cantons. Thus the provisions of the Swiss constitution have been changed repeatedly on many important points. In addition, even if the provisions of a rigid constitution remain unaltered, in the long run they often assume different meaning and scope. The "commerce clause" and the "due process clause" of the U.S. Constitution do not have the same legal implications today as they did 100 years ago. This is because formal constitutional provisions must be interpreted by the courts or by the legislature, the executive, and other institutional subjects. To a certain extent, interpretation inevitably involves adaptation of the letter of the law to the evolving needs and expectations of the community.

On the other hand, the constitutional law of countries with flexible constitutions must not necessarily be unstable and rapidly changing. Great Britain can modify all of its constitutional law by statute (or even in important areas by "conventions" between the supreme institutional powers of the state: the Crown, Parliament, the Cabinet). Nevertheless, statutes and common law principles of constitutional import cannot be changed as easily as other statutes and rules; they have a considerable capacity for permanence. For instance, the "rule of law"—roughly the equivalent of the American "due process" principle—has been an indefectible part of the British constitution approximately since the Glorious Revolution.

In sum, the relative continuity of a country's constitu-

tional law does not depend on the adoption of a rigid constitution, although such a constitution may make changes at times more complicated and difficult. It depends rather on the people's feelings about the fundamental political values the legal system ought to honour. If and when these feelings change, the change will be able to make its way sooner or later into the constitution, whether by using the amending process and the method of interpretation under a rigid constitution, or the easier ordinary legislative procedure or other methods under a flexible constitution (apart, of course, from the further possibility of a change, in both cases, through the extreme means of a violent revolution). Because the political values felt to be supreme by the dominant forces in a community have ultimate controlling influence, some European continental scholars have been prompted to call them the "material constitution," at any given historical moment, of that community. The developments of the material constitution are decisive in determining the retention or the demise, as well as the actual meaning and scope in application, of the principles and rules of the constitution, whether the latter is rigid or flexible.

Unitary, federal, and regionalist systems

THE DISTINCTION BETWEEN UNITARY, FEDERAL, AND REGIONALIST STATES

No modern state can govern a country only from a central point. The affairs of municipalities and rural areas must be left to the administration of local governments. Accordingly, in all modern states there are at least two levels of government: the central government and the local governments. But in a number of states between the two levels there exists still a third one consisting of governments that take care of the interests of, and rule over, more or less large regions.

Levels of government

The distribution of powers among different levels of government is an important aspect of the constitutional organization of a state. States with two levels of government can be distinguished on account of the greater or lesser autonomy they grant to the local level. Great Britain's respect for local self-government has always been a characteristic of its constitution. France instead, at least until recently, used to keep under strict central control its local authorities. In states with three levels of government the distribution of powers among the central and the intermediate governments varies. States formed through the union of formerly independent states usually maintain considerable legislative, executive, and judicial power at the intermediate level; the United States and Switzerland fall into this category. However, other states with three levels of government grant few powers to the intermediate level. This often happens in states that have introduced this level as a correction of their previous choice of two levels; this was done, for example, by Italy in its 1948 constitution.

States with two levels of government are called unitary, with three levels of the first category federal and with three levels of the second kind decentralized or "regionalist." These definitions, however, cannot be properly understood unless other elements characterizing the three types are mentioned and a tendency of the types to overlap is kept in mind.

The model federal state requires the existence, at the national level, of a written, rigid constitution guaranteeing not only the permanence and independence of the several intermediate governments but also the amplitude of their legislative, executive, and judicial powers. The national constitution must delegate to the central government only enumerated powers; the remaining powers are reserved to the intermediate governments. These (be they called states as in the United States or cantons as in Switzerland) must be represented as such, possibly on an equal footing, in a second chamber of the national legislature. They must also be allowed to participate somehow in the amending process of the national constitution. Such constitutional arrangements are at the same time the hallmarks of the genuine federal state and a guarantee against possible efforts of the central government to enlarge its jurisdiction and so imperil the important political role the intermediate governments must play in this kind of state. Formal constitutional safeguards, however, are not enough to preserve that role. Apart from constitutional amendments, the central government may always broaden its own sphere through the use of constitutional clauses granting "implied powers" or, more simply, through a suitable interpretation of the constitution by its own agencies (to which the final interpretation of the constitution is reserved). As a matter of fact, in the 20th century the balance in all federal systems has shifted toward central governments; intermediate governments have lost much of their previous exclusive rights and political weight. The shift was caused by the growth of governmental intervention in the economy and by the development of welfare measures: neither could take place without substantial involvement of the centre. An increase in the powers of the central government does not by itself impair the federal nature of the state if it keeps within certain boundaries. Beyond these boundaries, however, no matter what the formal constitutional principles seem to indicate, the federal state tends to become in fact a regionalist state.

The regionalist state

Regionalist states are also based, as a rule, on written, rigid constitutions granting some limited legislative and administrative (seldom judicial) powers to the intermediate or regional governments. But because regional governments possess jurisdiction only over enumerated matters, and even there are subject in part to the overriding powers of the national authorities, their actual role and political weight within the system largely depend on the will of the central government to buttress or to restrict their autonomy. Where the powers attributed by the constitution to the regional governments are particularly exiguous, the regionalist state will look in many respects like a unitary state. Where the powers are relatively large and the central government favours their expansion, the state tends to assume federal connotations even if the typical hallmarks of the federal system are not there.

In general, regionalism recommends itself in situations where the need is felt for a strong, all-controlling national government but the territorial extension of the country is great or the country is divided into sections with different ethnic, linguistic, or social characteristics (the last is the case of Belgium). Regionalism has also offered itself as a solution to unitary states that have decided to introduce regional governments in order to reinforce their democratic features or to alleviate the evils of an overcentralized bureaucracy (the case of Italy).

CLASSIFYING STATES AS FEDERAL, REGIONALIST, AND UNITARY

Classifying a particular state as federal, regionalist, or unitary may at times be difficult.

The United States and Switzerland are clearly federal states, although the role respectively of states and cantons has shrunk much since World War I: all of the abovementioned characteristics of the federal state are present in their constitutional systems. Canada is also a federal state, despite the fact that at least one of the formal marks of perfect federalism is absent from its 1982 constitution: the provinces' powers, not the central government's, are enumerated. But the provinces' powers are vast, and the guarantees for the provinces' independence and rights anchored in the constitution are particularly strong. For the same reasons Australia too can be considered a federal state. The Federal Republic of Germany is federal in all respects. Yet the legislation of the *Bund,* the central government, extends over so many matters that it is questionable whether Germany is not in fact a regionalist state. The question is even more open as regards India. The Indian federal constitution spells out a long list of important subjects over which the states and territories that compose the union have exclusive jurisdiction. But the constitution gives the central government the power to legislate on any subject—including the ones reserved to the regional governments—if it deems the matter of national importance. In addition, the central government has direct powers of control over the regional governments: *e.g.,* the national Parliament can dissolve the legislative

Germany and India

council of any state or territory. Similar remarks can be made with respect to the federal structure of many Latin-American states. The former Soviet Union was, by constitution, a federal state; but, apart from the question of the "nominal" value of at least certain parts of its constitution, the constitutional role entrusted to the Communist Party had such unifying effects on the whole system that the Soviet state could probably be defined at best as a regionalist state.

Italy and Spain

Italy and Spain are states with regional governments. These, by constitution, are endowed with legislative and administrative powers in certain areas (the courts are all national). Italy, however, is perhaps the best example of how a regionalist state may closely resemble a unitary one. The constitution grants limited powers to the regions. Parliament has extended these limits by devolving additional matters to the purview of regional legislatures. But regional laws must respect general principles laid down in national statutes, and in practice little room is left for really autonomous regional legislation. The regions, moreover, are not financially independent. Thus, all in all, they might almost be considered a branch of the system of local governments, together with communes and provinces, rather than a distinct, third level of government.

Great Britain and France are unitary states. Northern Ireland had special autonomy within the United Kingdom until restrictions were introduced to cope with the emergency situation in that region, and Scotland and Wales would have had special autonomy but in referendums their people rejected the devolution plans offered by the British Parliament. Had the plans been accepted, Great Britain would have become in part a regionalist state, though Parliament, under a flexible constitution, might, in theory, have later repealed the grant of autonomy. France in 1982 established by statute elective regional governments (*régions*) as part of a more general reform intended to make the system of local governments less dependent on the centre. *Régions* have fewer powers than the Italian regions, but their role may grow with time.

INTERNATIONAL UNIONS OF STATES

Finally, mention must be made of a growing tendency among national states to allow the direct operation within their constitutional systems of the laws of the international community and of the laws of special international organizations to which they belong.

The constitutions of Germany (article 25) and of Italy (article 10) provide that the legal system must conform with international customary law. Because both are rigid constitutions, this means that ordinary national statutes conflicting with that law are unconstitutional.

International unions and a new level of government

At times unions are formed among national states that, without unifying the member states into a new political community in the strict sense of the word, nonetheless set up governmental agencies whose laws immediately become part of the national systems. It is as if in the national constitutional frameworks a new level of government were added, from above, to the ones already existing. The most important example is the European Community (EC). Under the Treaty of Rome (1957) it has its own government consisting of a commission, a council of ministers, a parliament, and a court. It can issue regulations on economic matters indicated by the treaty. Up to now, EC regulations have been issued only if in fact consented to by each of the executives of the member states. Once in force, however, they must be applied by the national courts with precedence over national legislation. The binding interpretation of the treaty and of EC regulations belongs to the EC court, where it is possible for individuals to have recourse.

The EC may be the embryo of a future federal state, if the union develops into an organization whose central government is capable of making decisions independently of the will of member states (which for the moment it is not) and if it assumes functions in the field of foreign and military policy (which at present it does not possess). The community may also never become a federal state. But even as it exists now, it is much more than a simple international alliance of national states that have in common economic interests and assume the obligation to respect the regulations of such interests made by some external agency. The structures of the EC penetrate deeply into the constitutional structures of the national member states, much in the same way as the structures of the central government do with respect to the member states in a federal system. Some features of federalism are already present in the relations between the EC and the states belonging to it. Just as in a federal system, community law prevails immediately in the areas assigned to it over national law; it is the "supreme law of the land," which the national judiciaries must prefer to the laws of their own states in case of conflict. Just as in a federal system, the interpretation of EC law is reserved to a central government agency (the community court), whose decisions are directly binding for the member states and their courts. A member state, however, may always withdraw from the union if it chooses to do so, unlike a state member of a true federal system. But until it takes such a step, its subjection to the law of the EC is practically the same as that of a member state to federal law in a federal system. (G.B.)

Executives and legislatures

THE CONSTITUTION AND THE EXECUTIVE

States may be classified as monarchical or republican. From another point of view they may be described as having presidential or parliamentary executives (see below).

Though the institution of monarchy is as old as recorded history, the modern age has been moving steadily in the direction of republican government. Today, there are fewer than 30 monarchies. Many monarchs, as in Great Britain, Japan, the Scandinavian countries, and the Low Countries, are best described as constitutional monarchs; they are mainly titular heads of state and do not in fact possess important powers of government. Most of the executive powers are in the hands of ministers, headed by a prime minister, who are politically responsible to the parliament and not to the monarch. The executive powers of government in Great Britain, for example, are exercised by ministers who hold their offices by virtue of the fact that they command the support of a majority in the popularly elected House of Commons. The monarch can act only on the advice of the ministers and cannot exercise an independent will. The position of the monarchs in Scandinavia and the Low Countries is similar to that of the British: they reign but do not rule. In countries where no political party has a majority of its own in the parliament, the monarch may exercise some discretion in deciding whom to invite to serve as prime minister and to form a government. Even so, since the monarch must first consult with the various party leaders, he is not likely to have much discretion. In a country with a stable two-party system, all the monarch can do is offer the prime ministership to the leader of the majority party. Since 1975 the Swedish king has not even possessed this formal power; it is the president of the legislative assembly who chooses and appoints the prime minister. A constitutional monarch is the head of the state, not of the government. Standing above party and the active political controversies of the day, the sovereign is a focus of national loyalty and a useful symbol of the nation's unity and its historical past.

Monarchy

In a few monarchies, however—for example, those of Jordan and Saudi Arabia—the king exercises real powers of government. The ministers are chosen by and are responsible only to the king rather than to some elective parliamentary body. Hereditary rulers with this degree of personal power were quite common in the 18th century, but they are rare today.

Far more significant than the distinction between monarchy and republicanism is the contrast between presidential and parliamentary executives. Since the United States has for long been the world's leading exponent of presidential government and Great Britain the oldest and most successful practitioner of parliamentary government, their systems may be taken as models with which the systems of other countries can be compared.

The U.S. system is based upon a strict concept of separation of powers: the executive, legislative, and judicial

powers of government are vested by the Constitution in three separate branches. The president is not selected by Congress, nor is he a member of Congress. He has a fixed term of office of four years, and he holds it no matter how his legislative program fares in Congress and whether or not his political party controls either or both houses of Congress. The members of the Cabinet are chosen by the president and are politically responsible to him. The Constitution does not permit them to be members of Congress; it provides that "no Person holding any Office under the United States, shall be a Member of either House during his Continuance in Office."

The British Parliament

The parliamentary executive system proceeds upon different assumptions. In Great Britain, whose system many countries have chosen to emulate, the executive officers of the state are not entirely separated from the legislative branch. On the contrary, the British Cabinet may be described as the leading committee of Parliament. Although the prime minister, the head of the government, could at one time hold a seat in either the House of Lords or the House of Commons, the contemporary convention is membership in the House of Commons. The other ministers who make up the Cabinet must be members of one or the other house of Parliament. If the prime minister wants someone who is not in Parliament to serve in the Cabinet, he must either appoint him to the peerage or find a vacancy in the House of Commons to which he can be elected.

Whereas in the U.S. system, with its separation of powers, the chief executive and the Cabinet officers are institutionally apart from the legislature, in Great Britain the ministers of the crown hold their powerful executive positions only so long as they enjoy the support of a majority of the House of Commons. A Cabinet that loses that support must either dissolve the House and call a new election, thus in effect putting the issue to the voters, or resign and permit others to form a government. In the 20th century most changes in power have occurred as a result of the outcome of a general election.

It follows that in the British Parliament the prime minister and the Cabinet are fully in charge. They are responsible, as the guiding committee of Parliament, for the preparation and enactment of most legislation and of the budget. There can be no permanent or serious conflict between the House of Commons and the Cabinet, for responsibility means that the government of the day must either prevail or give way to another government. Thus the deadlocks between the chief executive and the Congress that are a frequent occurrence in the United States cannot occur under the parliamentary system.

A system may appear to be parliamentary or presidential without actually being either. In Latin-American and African states many presidential systems have been converted into military dictatorships. The former Communist governments of central and eastern Europe were parliamentary in form, but power was effectively in the hands of a party leader. The fact that the head of state is called a president does not mean that the system is presidential. The head of the Italian state, for example, is a president elected for a seven-year term by a joint session of Parliament, but the executive power is in fact exercised by a prime minister and other Cabinet ministers who are responsible to Parliament. In former monarchies that now have parliamentary systems the abolition of monarchy invariably led to the substitution of a president for the hereditary ruler.

Hybrid forms

There are some hybrid forms of government that combine features of both presidential and parliamentary systems. France's Fifth Republic (1958) is a good example. According to the terms of a constitutional amendment adopted in 1962, the president of the republic is elected by direct vote of the people for a seven-year term. This gives the president an enormous moral power derived from the fact that he is a product of universal suffrage. Although in the exercise of some powers the president needs the signature of the prime minister or of some other minister, he has great substantive powers of his own: he appoints the prime minister; he dominates the management of foreign relations; he may dissolve the National Assembly, though not more often than once a year; and he possesses vast emergency powers. The cabinet, called the Council of Ministers, is presided over by the president. Members of the council cannot be members of Parliament, but they have access to both chambers; and they may speak there, though they do not vote. The council is responsible to the National Assembly and can be defeated by censure motion. Thus the French system of government is neither presidential nor parliamentary in form; it combines elements of both in a unique fashion.

The governmental system of the Federal Republic of Germany is mainly parliamentary, but with some interesting variations. The head of state is the president, elected for a five-year term by a body known as the Federal Assembly, which consists of members of the lower house of Parliament (the Bundestag), plus an equal number of representatives elected by the *Länder* (the regional subdivisions of the national state). The head of government is the chancellor, who must have majority support in the Bundestag; but only he, and not the Cabinet, is responsible. The Bundestag can express its lack of confidence in the chancellor only by electing a successor by majority vote. In this fashion it was hoped to eliminate some of the weaknesses of the Weimar constitution of the post-World War I period. The chancellor may seek a vote of confidence, and if he fails he may ask the president to dissolve the Bundestag and call a new election.

The governmental system of India is more typically parliamentary in form. The president is elected for a five-year term by an electoral college consisting of all members of the national Parliament and of the state legislative assemblies. The president can act only on the advice of ministers who are responsible to Parliament. The lower house, the House of the People, is subject to dissolution.

The Swiss executive is unique. The Federal Council consists of seven members elected for four-year terms by the parliament (the Federal Assembly). They are elected as individuals, and they are never forced to resign; in fact, they are almost always reelected, some serving for as long as 25 to 30 years. A disagreement with the Federal Assembly leads neither to resignation of the Federal Council nor to a dissolution of the parliament; the ministers simply adjust their positions to conform with the wishes of the parliamentary majority. This does not mean that the Federal Council is not an important body; as a group, it originates most new legislation, and its members, as individuals, head up the great departments of government. Each year the parliament appoints a member of the Federal Council to serve as president of the confederation. The president is chairman of the Federal Council and titular head of state. Although this system has not been adopted in other countries, it has worked well for the Swiss.

UNICAMERAL AND BICAMERAL LEGISLATURES

A central feature of any constitution is the legislature. It may be a unicameral body with one chamber or a bicameral body with two chambers.

Unicameral legislatures are to be found in small states with unitary systems of government, among them Denmark, Sweden, Finland, Israel, and New Zealand, or in very tiny states such as Andorra, Luxembourg, and Liechtenstein. They are also found in newly independent states undergoing rapid social and political change, such as some Third World states, and in Socialist countries, where unicameralism is a feature deriving from the Communist concept of the appropriate organization of political power.

Bicameralism and federalism

Federal states, whether large or small, have bicameral legislatures, one house of which represents the main territorial subdivisions. The classic example is the Congress of the United States, which consists of a House of Representatives of 435 members elected for two-year terms from single-member districts of approximately equal population and a Senate consisting of two persons of each state elected by the voters of the state. The fact that all states are represented equally in the Senate, regardless of their size, stems from the federalistic character of the American union. The U.S. Senate enjoys special powers not shared by the House of Representatives: it must authorize by a two-thirds majority vote the ratification of international

treaties concluded by the president and must confirm the appointments of the most important federal officers made by the president.

The federal character of the Swiss constitution is likewise reflected in the makeup of the nation's central legislature, which is bicameral. One house, the National Council, consists of 200 members apportioned among the cantons according to population; the other house, the Council of States, consists of 46 members elected by direct ballot—two from each canton. The Canadian Parliament is also bicameral, just as is the Australian.

Bicameralism is also characteristic of governmental systems that are best described as regionalist. Here, too, bicameralism is expressive of the territorial subdivisions that are joined together to form the national state. The parliament of the Federal Republic of Germany includes a Bundestag elected by general suffrage and a Bundesrat appointed by the 16 *Länder*. Since most members of the Bundesrat are ministers in the *Land* governments, the chamber is a significant link between the *Länder* and the central government. The Parliament of India includes a Council of States and a House of the People, the former elected by the state legislative assemblies and the latter elected directly from territorial constituencies.

Bicameralism and unitary systems

A unitary governmental system does not imply unicameralism in the legislature. Most legislatures of unitary states are, in fact, bicameral, though one chamber is usually more powerful than the other. This is true for the world's oldest and most successful parliament, that of Great Britain, which consists of the House of Lords and the House of Commons. The House of Commons has become by far the more powerful of the two chambers, and the Cabinet is politically responsible only to it. The House of Lords has no control over finances and with respect to other legislation only a modest suspensory veto, which can be easily overcome in the House of Commons by a second vote at an early date. The parliaments of Italy, Japan, and France are also bicameral. In the United States all of the 50 states except Nebraska have bicameral legislatures, even though their governmental systems are unitary. In all states the two houses have equal legislative authority, but the so-called upper houses, usually called senates, have the special function of confirming the governors' appointments. (G.B./D.Fe.)

Judicial review

From the United States came the first examples of written, rigid constitutions. The United States gave the world another institution that has become a fundamental feature of many contemporary constitutional systems: judicial review.

Under rigid constitutions it is possible to have special state agencies control the conformity of ordinary legislation with the rules of the constitution and, in case of conflict, set the former aside. Under a flexible constitution this cannot happen; in Great Britain, statutes, even if contrary to long-established constitutional principles, are binding for everybody and can be set aside only by subsequent statutes repealing them. The power to invalidate legislation conflicting with the provisions of a rigid constitution can be entrusted either to some particular political organ of the state or to the judiciary. A political organ endowed with such power was, for example, the Senate (Sénat Conservateur) under the French constitutions of 1799 and of 1852. Although some precedents existed in the constitutional history of other countries, it was in the United States that the idea of making the judiciary the guardian of the constitution first took definitive shape. Judicial review—the power of courts to rule on the constitutional validity of legislation—has the advantage over political review in securing more impartial judgments, supported by reasons articulated according to traditional, tested rules of legal interpretation.

JUDICIAL REVIEW IN THE UNITED STATES

Because U.S. judicial review has been a model for other countries, it is appropriate to devote a few words to it and the body of constitutional law it has produced.

Judicial review is not explicitly mentioned in the U.S. Constitution and is itself a product of judicial construction. The Supreme Court argued in *Marbury* v. *Madison* (1803) that because the Constitution is the supreme law of the land (it says as much in Article VI) and because it is the province of the judiciary to uphold the law, it follows that, when state laws and even acts of Congress are inconsistent with a provision of the Constitution, the former must yield to the latter and must be declared void by the courts. The same principle holds, of course, with regard to executive action contrary to the Constitution. Supreme Court pronouncements on questions of constitutionality are final and binding for all other courts and governmental authorities, state and federal.

Marbury v. *Madison*

In the U.S. system of judicial review, constitutional questions can be raised only in connection with actual "cases and controversies." Advisory opinions to the government are not rendered by the courts. Although the requirements to litigate cases have been relaxed by the Supreme Court, the rule still is that courts will not decide a constitutional question unless it is rooted in a controversy in which the parties have a direct, personal interest; this can sometimes frustrate efforts to obtain pronouncements on disputed issues. In the American system courts, moreover, are the guardians of the Constitution, but they are not bound to consider all the provisions of the Constitution justiciable. Under the doctrine of "political questions" the Supreme Court has refused at times to apply standards prescribed by or deducible from the Constitution to issues that it believed could be better decided by the political branches of government. For instance, Article IV, 4, provides that the states must have a republican form of government. Since *Luther* v. *Borden* (1849) it is settled that the court will not use the provision to invalidate state laws; it is for Congress and the president to decide whether a particular state government is republican in form. Many military and foreign policy questions, such as the question of the constitutionality of a particular war, have been likewise considered political and therefore nonjusticiable.

Judicial review is more impartial than political review. This does not mean that it is entirely immune to political considerations of a general, abstract nature and to the impact of the evolution of the people's needs and of their political attitudes. As a matter of fact, the Supreme Court's reading of the Constitution has itself evolved in the course of two centuries in concomitance with the large transformations that have occurred in American society.

Given the nature of the U.S. constitutional system, the Supreme Court must see to it that the Constitution is respected and applied in three main areas: the relations between the states and the national government, the separation of powers within the national government, and individual rights. In each of these areas the court's conception of the Constitution has undergone substantial changes.

The federal system

In the first half of the 19th century the Supreme Court succeeded in reinforcing the newly born structures of the federal system by interpreting generously those provisions of the Constitution that concern federal judicial power and those that set limitations on the states' powers to regulate interstate commerce. Later, when Congress began to enact laws intended to regulate some aspects of the nation's economic processes, the court was very cautious in granting the necessary powers. Up to the New Deal years (1932–37), the court, while admitting several federal regulatory interventions, also ruled that some economic relations, such as labour relations, lay almost entirely outside the scope of the commerce clause (the clause that gives Congress the power to regulate "commerce among the states") and were therefore matters exclusively for state legislation. After 1937 the court lifted the obstacles it had previously erected to federal interventions in the economic and social transactions of the nation. Today, under the new interpretation of the commerce clause laid down in such decisions as *Wickard* v. *Filburn* (1942) and under the doctrine of the federal spending power first enunciated in *U.S.* v. *Butler* (1936), Congress can make laws with respect to practically all subjects it deems of national relevance and in need of regulation from the centre.

In the area of separation of federal powers the court has

Separation of powers

countenanced in the course of time a transfer of powers to the executive and to administrative agencies that probably was not envisaged by the Founding Fathers. Because all legislative powers are conferred by Article I, 1, of the Constitution upon Congress, the court at first ruled that such powers cannot be delegated by Congress to the executive. This doctrine was much diluted in the 20th century when it became clear that delegated legislation was necessary to govern a system of mixed economy. The court's attitude favourable to a reinforcement of the executive within the constitutional system has manifested itself also in other respects, notably in the field of foreign affairs. But the court has been able also to draw boundaries to an excessive expansion of the presidency. It has ruled that the president cannot, under the pretext of an emergency, disregard rules of conduct prescribed by Congress precisely for the circumstances of the case (*Youngstown Sheet and Tube Co.* v. *Sawyer,* 1952). It has established that the prerogative of the president to keep confidential statements secret must yield to the need of the judiciary to enforce criminal justice if the secret does not relate strictly to military or diplomatic matters (*Nixon* v. *U.S.,* 1973).

Rights of the individual

Until the New Deal the court used the provisions of the Constitution concerning individual rights primarily to protect property and economic liberties. That use helped to preserve a system of laissez-faire economy against state and federal efforts to interfere with the market. In particular, the "due process" clauses of the Fifth and Fourteenth amendments (no person shall be deprived of "life, liberty, or property, without due process of law") were often employed by the court to invalidate social legislation (*Lochner* v. *New York,* 1905; *Adair* v. *U.S.,* 1908). In the second half of the 20th century the posture of the court has changed entirely. The court today seldom concerns itself with economic liberties. It is engaged rather in protecting citizens' noneconomic freedoms as well as their equality before the law, focusing on issues such as civil and political rights, procedural rights in the criminal and administrative processes, or the right to privacy. In the course of developing this new jurisprudence the court has declared unconstitutional segregation in the schools (*Brown* v. *Board of Education of Topeka,* 1954) and malapportionment in electoral districts (*Baker* v. *Carr,* 1962; *Wesberry* v. *Sanders,* 1964); it has defended the rights of the suspect and of the accused (*Mapp* v. *Ohio,* 1961; *Miranda* v. *Arizona,* 1966); it has liberalized voluntary abortion (*Roe* v. *Wade,* 1973).

Viewed in the light of its two-century performance, U.S. judicial review can be assessed as an institution that defends the values of the political ideology prevailing in a given historical period against by and large occasional deviations from them on the part of the political branches of government. During the 19th and early 20th centuries, for example, the ideal of the minimal state and of a self-governing market was dominant with the elites of the Western world, and the Supreme Court did its best to enforce it in the peculiar context of the U.S. political system. At present the court is dedicated to furthering the values of the currently dominant ideal of a democracy: a system in which the equality and the noneconomic freedoms of persons are recognized and the state possesses all the necessary means to regulate the economy. Conflicts between the court and the political powers, state and federal, have occurred, but they have never been sharp except occasionally under particular circumstances: in the difficult years following the establishment of the new federal government and in the years of the Civil War; in the phase of transition from one to the other dominant political ideal (the New Deal years) and in the 1950s and 1960s, when the federal and state governments were seriously lagging behind in reshaping the legal system in accordance with fundamental requirements of the new democratic model.

JUDICIAL REVIEW IN EUROPE AND ELSEWHERE

In Europe and other parts of the world the idea of making the judiciary guardian of the constitution was adopted much later than in the United States, as a rule only in the 20th century. While adopting it, however, some European countries introduced a variant on the U.S. model. Instead of letting any court pass on the constitutionality of statutes with the Supreme Court having the final say, as in the United States, they chose to set up a special constitutional court to which all questions concerning the validity of legislation must be referred and which alone has the power to declare statutes unconstitutional. In continental Europe judges are usually career functionaries; it was thought that the delicate task of invalidating legislation would be better performed by a court whose members were appointed directly either by parliament or, in part, by the president of the republic, the executive, the highest ordinary courts, and so forth.

European constitutional courts

The U.S. system of judicial review is "decentralized"; whereas the system based on a special constitutional court is "centralized." Austria was the first to inaugurate the centralized system (1920). After World War II it was adopted by Italy (1948) and West Germany (1949). Constitutional courts are at work today also in Spain, Portugal, and Turkey. In European centralized systems constitutional questions concerning the validity of statutory law reach the court chiefly through references by the ordinary courts engaged in deciding cases or through appeals by the losing parties of ordinary courts' decisions depriving them of their constitutional rights. But sometimes the questions can be raised also by such political agencies as the national executive and the regional governments or by a parliamentary minority. These can attack the law before the constitutional court without having to sue in an ordinary court. In certain instances the centralized method probably makes judicial settlement of constitutional issues easier and quicker than in the United States. And the American doctrine of "political questions" does not seem to have found reception, at least as such, in the jurisprudence of European centralized systems. Besides adjudging the validity of statutory law, European constitutional courts usually must also resolve conflicts between state agencies (the legislature, the executive, the president of the republic, and the judiciary) disputing about their respective constitutional prerogatives. In addition, they may sit as judge in trials upon impeachments and dispose of other matters of constitutional import.

Since 1958 France has had a Constitutional Council, which, though not a true court, can set aside unconstitutional statutes before they are promulgated, upon petition by the president of the republic or by the prime minister, the chairman of either of the two legislative assemblies, or a parliamentary minority.

Judicial review in other countries

The U.S. system of judicial review by ordinary courts has been adopted, sometimes with partial modification, by several states both in Europe and elsewhere, including Ireland (1937), Greece (1975), Japan (1946), India (1950), Mexico (1917), Brazil (1946), and Argentina (1949). It has been in operation in Switzerland, with some limitations, since 1874. It was introduced in Canada in 1867 and in Australia in 1900 and is presently an important feature of their constitutions.

Communist countries, with the exception of Yugoslavia, do not admit judicial review in their constitutions. The reason adduced is that it would undermine the unity of political powers and the sovereignty of the people as interpreted by the legislature. Hungary in 1984 and Poland in 1985 set up constitutional councils, which, however, serve in practice only as consultative organs for the legislature.

TRENDS OF JUDICIAL REVIEW IN THE UNITED STATES AND IN EUROPE

Constitutional courts and supreme courts exercising judicial review outside the United States are often less politically influential than their American counterpart. Nevertheless, judicial review, wherever it is at work, has become an element of at least some weight in the constitutional processes of the state, and it tends in general to advance the same democratic values that have inspired the decisions of the U.S. Supreme Court since the 1930s.

European constitutional courts, in particular, have been able to correct here and there the legal system of their countries by reading the bill of rights present in their respective constitutions in ways that bear comparison with the American experience of judicial review. Sometimes, of

course, the trends of decisions diverge on special points, but the general direction seems to be the same. It may be remarked, however, that European courts have often been more cautious than the U.S. Supreme Court in expanding the freedoms of the individual at the expense of other competing values. A few examples will suffice.

Freedom of expression

In the area of freedom of expression the American doctrine of "clear and present danger," as restated in *Brandenburg* v. *Ohio* (1969), implies that no seditious or subversive speech can be punished unless it constitutes an incitement to immediate unlawful action and the incitement is likely to produce, in the circumstances, such action. The freedom to express unorthodox opinions is clearly recognized by European constitutions and is upheld by the constitutional courts when they are confronted with laws that curtail it. The doctrine of clear and present danger, however, has not been adopted by them. The Italian constitutional court requires, for the punishment of speech advocating the use of violence, that the speech create, in the circumstances, a "danger," but it does not specify that the danger must be "immediate." The West German constitutional court, judging on the basis of constitutional provisions that forbid speech directed at impairing the liberal-democratic foundations of the state and associations pursuing the same goal, dissolved in the 1950s a neo-Nazi and a Communist party without considering the element of actual "danger" relevant. Later it countenanced, on the same basis, laws excluding from public employment persons holding subversive beliefs. In the United States the law of libel concerning public figures actively protects free speech inasmuch as, under the doctrine of *New York Times* v. *Sullivan* (1964), plaintiffs cannot win unless they prove that the libeler acted with "special malice" (*i.e.*, knowingly asserted the false). No special malice is constitutionally required in Europe to find liability in cases of defamation of public figures.

Abortion

The U.S. Supreme Court found in *Roe* v. *Wade* that a woman is entitled by the Constitution to obtain an abortion freely, after consultation with a doctor in the first trimester of pregnancy and in an authorized clinic in the second trimester. No European constitutional court has gone that far in recognizing freedom of abortion as part of the woman's right to privacy. The Italian court held in 1975 that voluntary abortions cannot be punished if performed in view of saving the life and health, both physical and emotional, of the woman. The Austrian court (1974) and the French Constitutional Council (1975), without tackling the problem of a woman's constitutional right to interrupt pregnancy, have validated statutes that provide in liberal terms for the possibility of voluntary abortions. The West German court, instead, quite alone in Europe, ruled in 1975 that the constitution, by declaring the life of persons inviolable, implicitly wants also the life of fetuses protected and that an adequate protection is afforded by the state only if voluntary abortion is made a crime by law. But the law of East Germany was much more permissive, and, a few years after the reunification of the two German states (1990), the Constitutional Court, while reaffirming that on principle the fetus must be protected, held that the protection must be achieved not by punishing but by counseling and other measures aimed at influencing a woman to decide freely to carry her pregnancy to term.

Church and state

The U.S. Supreme Court considers the teaching of religion and even praying in public schools unconstitutional (*Engel* v. *Vitale,* 1962). Separation of church and state, although contemplated in principle also by European constitutions, is sometimes tempered by constitutional provisions making accords between church and state possible in matters of common interest. No European court has found that accords giving students the opportunity to attend religious courses in public schools violate the principle of religious freedom or the principle of the equality of all citizens before the law.

In other areas of the law European constitutional courts have proved to be as ready as, and sometimes even more ready than, the U.S. court to afford protection of the rights of the individual. In the United States *Mapp* v. *Ohio* established that illegally obtained evidence cannot be produced at a trial to substantiate criminal charges against the defendant. This "exclusionary rule" is in force at least partially also on much of the European continent. The Italian constitutional court has stated that it is required on constitutional grounds. *Miranda* v. *Arizona* ruled that a confession made by an accused under arrest cannot be used as evidence unless the accused has been previously advised of his rights, among which is the right to consult with a lawyer. The Italian constitutional court has declared unconstitutional (1970) a law that excluded the suspect's attorney at the interrogation by the investigatory authorities and at other proceedings intended to secure evidence against the suspect.

Right of action against the administration

Although as a rule courts in the United States can be asked to pass on the lawfulness of administrative action, the Supreme Court is still reluctant to establish as a matter of constitutional due process that citizens are always entitled to sue in court in order to have administrative decisions set aside if contrary to ordinary substantive or procedural rules. The Italian and German constitutions explicitly state the principle without admitting of any exception, and the courts of both countries carefully see to it that the principle is respected and that citizens are not deprived of their day in court even if the other party is the administration.

While applying the principle of equality in cases of sex discrimination and discrimination against illegitimate children, European courts have often displayed an activism superior to that of the U.S. Supreme Court in the same areas. The West German court, for instance, ruled in the 1970s that husband and wife must have the same rights within the family and that, in particular, parental power over the children belongs equally to both, the law not being permitted to prefer the husband's will in case of divergences of opinions; and this has remained the legal principle in force also in unified Germany. The Italian court has in many respects reshaped family law in order to ensure the equal rights of the wife and of children born out of wedlock. It has also defended the right of women to a treatment equal to that of men in labour relations. Effective legislative protection against discrimination of non-European immigrant workers and their families is still deficient in EU countries, and by and large constitutional courts have said little in this area. But they have shown in general remarkable sensitivity when the problem affects local ethnic or linguistic minorities. The U.S. Supreme Court, after having declared segregation unconstitutional, found that programs of "affirmative action" meant to help minorities to rise from their lower position in society did not constitute "reverse discrimination" even if they included some privileges in the access to university education (*University of California* v. *Bakke,* 1978) and in the conservation of jobs. A ruling analogous to this has come from the Italian court with regard to the treatment of the German-speaking population of Alto Adige. The court in the 1970s validated laws that provided for reserved "quotas" in public employment and publicly financed housing with a view of preserving the integrity of that linguistic group in the region they had inhabited for centuries.

It is true that thus far European courts have never openly defied the political powers of the state in the way the U.S. Supreme Court has sometimes done. But the greater prudence of European courts is not difficult to explain. It depends on many causes, prominent among which are the facts that their legitimation as independent and active agencies within the political system is recent and that the tradition of judicial review does not yet have in Europe the firm roots it possesses in the United States.

TRANSNATIONAL JUDICIAL REVIEW

Judicial review has also transcended the boundaries of the national state. All western European states except Finland have ratified a convention on civil and political rights, first signed in 1950. On the basis of the convention a commission was organized in Strasbourg, Fr., to which individuals can appeal against actions of a member state that violate rights protected by the convention. The commission and a member state can ultimately refer the issue to a court, the European Court of Human Rights, for a final decision. The court, besides granting a remedy in

the pending case, may find statutory and other national laws contrary to the provisions of the convention, and the state concerned is under an obligation to adapt its legal rules to the principles stated by the court. Great Britain too has accepted this special jurisdiction of the European Court of Human Rights; this means that in its political system possible legislative encroachments on individual rights can now be rebuked by a judicial agency, though not a national one. In countries having an internal system of judicial review the European protection is added to that provided by the national system.

The decisions of the European Court of Human Rights are important because they may gradually work as a factor that will unify this branch of the law throughout Europe. Some national constitutional courts, notably the Austrian court, already pay particular attention to the jurisprudence of the European court. So does the court of the European Community, which while not having to apply a community bill of rights (the Treaty of Rome contains none) must nevertheless take into account the problems of fundamental rights in developing the economic law issuing from the legislative organs of the EC.

A convention on human rights similar to the European one was signed by several Latin-American states at San José, Costa Rica, in 1969. A court having jurisdiction over individual complaints began functioning in 1982.

Thus the idea of the rights of the individual, after having contributed three centuries ago to the birth of the modern constitutional law of the national state, has now become the mainspring of another incipient, promising experience: judicial review with transnational dimensions. (G.B.)

Continental Landforms

Continental landforms are the surface features of the largest land areas of the Earth. Such structures are rendered unique by the tectonic mechanisms that generate them and by the climatically controlled denudational systems that modify them through time. The resulting topographic features tend to reflect both the tectonic and the denudational processes involved. The most dramatic expression of tectonism is mountainous topography, which is either generated along continental margins by collisions between the slablike plates that make up the Earth's lithosphere or formed somewhat farther inland by rifting and faulting. Far more subtle tectonic expressions are manifested by the vast continental regions of limited relief and elevation affected by gentle uplift, subsidence, tilting, and warping. The denudational processes act upon the tectonic "stage set" and are able to modify its features in a degree that reflects which forces are dominant through time. Volcanism as a syn-tectonic phenomenon may modify any landscape by fissure-erupted flood basalts capable of creating regional lava plateaus or by vent eruptions that yield individual volcanoes.

The denudational processes, which involve rock weathering and both erosion and deposition of rock debris, are governed in character by climate, whose variations of heat and moisture create vegetated, desert, or glacial expressions. Most regions have been exposed to repeated changes in climate rather than to a single enduring condition. Climates can change very slowly through continental drift and much more rapidly through variations in such factors as solar radiation.

In most instances, a combination of the foregoing factors is responsible for any given landscape. In a few cases, tectonism, some special combination of denudational effects, or volcanism may control the entire landform suite. Where tectonism exists in the form of orogenic uplift, the high-elevation topography depends on the nature of denudation. In humid or glacial environments whose geomorphic agencies can exploit lithologic variations, the rocks are etched into mountainous relief like that of the Alps or the southern Andes. In arid orogenic settings, the effects of aggradation and planation often result in alluviated intermontane basins that merge with high plateaus interrupted or bordered by mountains such as the central Andes or those of Tibet and Colorado in the western United States.

In continental regions where mountainous uplifts are lacking, denudational processes operate on rocks that are only slightly deformed—if they are sedimentary—and only moderately elevated. This produces broad basins, ramps, swells, and plains. These are most thoroughly dissected in rain-and-river environments (sometimes attaining local mountainous relief on uplifts). Elsewhere, they may be broadly alluviated and pedimented where mainly arid, or widely scoured and aggraded where glacial.

Minor denudational landforms are superimposed on the major features already noted. Where aridity has dominated, they include pediments, pans, dune complexes, dry washes, alluvial veneers, bajadas, and fans. Ridge-ravine topography and integrated drainage networks with associated thick soils occur where humid conditions have prevailed. Combinations of these features are widespread wherever arid and humid conditions have alternated, and either category may merge laterally with the complex suite of erosional and depositional landforms generated by continental glaciers at higher latitudes.

This article deals with the major continental landform categories of each type. It describes the main topographic expressions, probable modes of origin, and distribution with respect to continental configurations. In addition, it reviews the significant theories of landform genesis developed during roughly the past two centuries.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 212, 231, and 232.

This article is divided into the following sections:

THEORIES OF LANDFORM EVOLUTION

General observations

BASIC CONCEPTS AND CONSIDERATIONS

Landform evolution is an expression that implies progressive changes in topography from an initial designated morphology toward or to some altered form. The changes can only occur in response to energy available to do work within the geomorphic system in question, and it necessarily follows that the evolution will cease when the energy is consumed or can no longer be effectively utilized to induce further change. The latter steady state, or dynamic equilibrium, situation will then continue with little topographic change until the prevailing conditions cease or are disrupted, so that a new evolutionary sequence can begin.

The English poet Alfred, Lord Tennyson once wrote:

> The hills are shadows, and they flow
> From form to form, and nothing stands;
> They melt like mist, the solid lands,
> Like clouds they shape themselves and go.

Tennyson's verse speaks well of the geomorphic necessities of time and landform change. Even the ancients were well aware of the ongoing effects of gravity, and it has long been realized that, given time and in the absence of opposing forces, gravity would pull the Earth's surface roughness down to form a featureless subaqueous spheroid. Such an evolution would be simplicity in the extreme and may in fact foretell the eventual destiny of terrestrial landforms when internal processes that generate relief cease to operate some billions of years hence in response to growing entropy in the system.

Even now in regions where the uplifting and relief-creating mechanisms have been inoperative for several hundreds of millions of years, the lands have been reduced by denudation to low and often nearly featureless plains. Yet, it is clear that any modern theory of landform evolution must take into account the possibility of a periodic regeneration of continental elevations, particularly of large-scale relief features. For without such regeneration, there would be no continents or mountains even today, given their present rates of erosional destruction.

The history of landscape evolution theory is one of adapting concepts to new evidence of increasing complexity. This situation is quite apparent in the way thinkers and scientists have dealt with the processes within the Earth that oppose gravity and re-create land elevation and roughness. The existence of such processes was implicit in the writings of Xenophanes of Colophon (*c.* 570–*c.* 478 BC), Herodotus (*c.* 484–420? BC), and Leonardo da Vinci (AD 1452–1519). The culmination of ideas of continental renewal and relief genesis is found in the isostatic theory formulated by John Henry Pratt and George Biddel Airy of England during the mid-1800s and in the concepts of plate tectonics put forth by Harry H. Hess and Robert S. Dietz of the United States during the early 1960s. Periodic resurrection of the surface roughness of the Earth is an event that geologists continually plot, widely accept, and increasingly understand.

Continental renewal and relief genesis

Over the years there have been many other ideas that have posed complications for geomorphic theory. Notable among these were notions of continental submergence by seas (proposed by Georges-Louis Leclerc, comte de Buffon, about 1750), which had implications of relative sea-level changes and sedimentary leveling of submersed areas.

Theoretical matters were complicated further by suggestions during the 19th century that iceberg rafting of gravel during Noah's Flood accounted for glacial "drift." Since that time, the Noachian Deluge has lost much of its geomorphic appeal. Yet, sedimentary deposits laid down in ancient inland seas are widely acknowledged to account for much continental bedrock, and they underlie and create vast structural plains in areas such as Australia.

The role of climate in landform evolution

The geomorphic implications of volcanism were already widely appreciated in the 1700s, though they were not well integrated into modern tectonic mechanisms until 1961. Climate, however, is another story. Glacial theory was introduced during the early 1800s and was seen by many to have climatic and geomorphic implications. Nonetheless, the most popular theory of landform evolution of the past century, that proposed by the American geologist and geographer William Morris Davis (*c.* 1899), relegated continental glaciation to accidental status and gave no real consideration to the geomorphic effects of non-glacial climates. Until about 1950 this Davisian view held sway in geomorphology. Since then, research has shown beyond question that a variety of climatic effects can have a profound influence on landscape, that climates change (often with great frequency and intensity), and that virtually none of these events can be termed accidental.

CONSTRAINTS ON MODERN LANDFORM THEORY

Rather than merely trace the hit-or-miss development of geomorphic ideas from their beginnings roughly two centuries ago, it seems preferable to cite here those conditions firmly determined by intensive research that must serve as constraints for any modern theory of landform evolution. A brief mention of the postulates of earlier theorists will then show immediately what they accomplished, ignored, failed to consider, or were ignorant of. In sum, a modern theory of landform evolution must contend with the following well-established factors:

(1) Continents consist of a craton of crystalline rocks 1,000,000,000 to 3,000,000,000 or more years old, have been periodically submerged by epicontinental seas, and are in most cases locally covered with veneers of nearly flat-lying sedimentary rocks.

(2) Where orogenic events were involved less than 500,000,000 years ago, mountainous elevations and relief containing deformed rocks exist on continents.

(3) Lowering of the land by denudational processes is accompanied by essentially continuous isostatic adjustment by load-compensating uplift.

(4) Mountainous relief of the continent-to-continent collision type (*e.g.,* the Appalachian Mountains of eastern North America) can eventually be eliminated by erosion, whereas trench-type mountains (*e.g.,* the Andes of western South America) probably cannot as long as the associated trench subduction system endures.

(5) Climates on lands vary through time in response to lateral continental drift of 0–12 centimetres (0–5 inches) per year. North America, for example, is moving northwest at a rate of about three centimetres per year. On the other hand, Antarctica is hardly moving and has been in a polar position undergoing glaciation for about 30,000,000 years.

(6) Over most lands, climates also vary with atmospheric, oceanic, and solar factors in cycles lasting thousands of years (the Milankovitch solar radiation cycle, for example, has a duration of ± 25,800 years).

(7) In select hydrographically favoured sites on time scales not influenced by continental drift (*e.g.,* Antarctica), climates on continents or portions thereof can remain essentially constant for periods of millions of years.

(8) Since geomorphic processes under arid, humid, glacial, and possibly other climate conditions can induce particular landforms, areas subject to periodic climate change often show polygenetic landform associations.

(9) Landforms exposed for millions of years to a constant environment may display a climax (steady-state) landform association that is essentially timeless and in which landform evolution through denudation is reduced to mere negative allotropic growth.

(10) Since volcanism is seemingly localized in accordance with mobile heat-dispersal patterns within the Earth, eruptive effects may be imposed on any surficial geomorphic system at any stage of development.

(11) Similarly, mobile tectonic patterns involving rock deformation may be brought to bear on any surficial geomorphic system, with resulting relief, elevation, and topographic changes.

(12) Impacts on planetary surfaces by falling meteoroids,

asteroids, and cometary bodies are periodic but are capable of generating landforms of mountainous proportions. Such impacts are apparently diminishing in frequency and scale with time.

(13) Surficial geomorphic agents of denudation responsible for many, if not most, landforms include mass wasting, running water, glacial ice, and wind. They are not all of equal significance in every climatic setting, however.

(14) The geomorphic agents respond to various climates, changing in character and effect. They also respond in some degree to altered conditions of elevation and relief.

(15) The behaviour of denudational agencies and related geomorphic processes is neither constant nor linear in nature. Rates vary from long-term, imperceptible, and gradual to brief, rapid, and catastrophic.

(16) Changes produced by geomorphic agents vary in magnitude but not directly with time—*i.e.,* the same change involving the same energy expenditure may be either slow or fast. (Studies of river systems, for example, suggest that greater changes in channel morphology occur during brief infrequent floods than during protracted low-flow periods.)

(17) Perturbations in geomorphic processes or environments cause accelerated changes in most landform configurations, soils, and deposits, which eventually slow down as new equilibrium forms develop.

(18) A given landform or deposit is only stable in association with its formative process and environment, and in any subsequent alternative setting it begins to change toward a new equilibrium morphology.

(19) In a denudational setting, slope as an influence over process rate may be subordinated to such factors as runoff volume, soil-moisture content, bedrock coherence, ground-cover type, channel roughness, channel cross section, weathering type, sediment calibre, and sediment quantity.

(20) When climate in a region changes, elimination of relict landforms and deposits causes a disequilibrium phase, which is followed by a dynamic equilibrium phase as new geomorphic equilibria are established. The disequilibrium phase may range from a few score or hundred years for certain organic responses to many thousands of years for soil, hillslope, or drainage adjustments.

(21) Certain landforms can only develop when a particular climatic sequence ensues. For example, major marine deltas form on rivers that drain newly humid regions following glaciation or aridity; streams from regions that have long been humid have no deltas.

(22) Some landforms or deposits, once formed, strongly resist subsequent changes regardless of climatic history—*e.g.,* entrenched meanders such as those that exist in parts of the Appalachians, chert felsenmeers (accumulations of rock blocks) like those in the southern Ozark region of the United States, and duricrusts of the type commonly found in Australia.

(23) No such thing as an "average" terrestrial climate seems to exist, and certainly a climatic "norm" for one continental configuration would differ from that for another—*e.g.,* the supercontinent Pangaea of pre-Cretaceous times (more than 136,000,000 years ago) differed climatically from its subsequent fragments for both the Cretaceous (136,000,000 to 65,000,000 years ago) and the present.

(24) Sea level has been found wanting as a stable limiting datum for erosional processes or as an influence on stream behaviour. Glacioeustatic fluctuations on the order of 130–150 metres appear to have been commonplace during the continental glacial sequences of the Carboniferous (345,000,000 to 286,000,000 years ago), Pleistocene (2,000,000 to 10,000 years ago), and at other times, and periodic dessication of restricted ocean basins has occasionally permitted major rivers to deepen their courses thousands of metres below mean sea level.

(25) The Earth and the solar system as a whole are at least 4,500,000,000 years old. This is long enough for some geomorphic phenomena to occur several times but probably not long enough for others to happen even once. Certainly it is doubtful if more than nine collision-type mountain systems can have been eroded away in one spot, even if it were possible for them to form there.

Historical survey

Some of the more significant landform theories of the past 200 years or so are considered here, with particular attention to the degree to which they reflect the list of geomorphic constraints cited above. It should be noted that most early theorists operated within the chronological limitations imposed by theologians. During the 17th century, for example, Archbishop James Ussher of Ireland added up the ages of men cited in the Old Testament of the Bible and concluded that the creation had occurred in 4004 BC. John Lightfoot, an English divine and Hebraist, was so stimulated by this revelation that he additionally observed that the exact time was October 26 at 9:00 AM! This meant that all of the Earth's surface features had to have been formed in less than 6,000 years. Given this time frame, geomorphologists could explain the genesis of landforms in only one way—on the basis of catastrophic events. Everything had to occur quickly and therefore violently.

LANDFORM THEORIES OF THE 18TH AND 19TH CENTURIES

Catastrophism. During the late 18th and early 19th century, the leading proponent of this view was the German minerologist Abraham Gottlob Werner. According to Werner, all of the Earth's rocks were formed by rapid chemical precipitation from a "world ocean," which he then summarily disposed of in catastrophic fashion. Though not directed toward the genesis of landforms in any coherent fashion, his catastrophic philosophy of changes of the Earth had two major consequences of geomorphic significance. First, it indirectly led to the formulation of an opposing, less extreme view by the Scottish scientist James Hutton in 1785. Second, it was in some measure correct: catastrophes do occur on the Earth and they do change its landforms. Asteroid impacts, Krakatoa-type volcanic explosions, hurricanes, floods, and tectonic erosion of mountain systems all occur, may be catastrophic, and can create and destroy landforms. Yet, not all change is catastrophic.

Uniformitarianism. The Huttonian proposal that the Earth has largely achieved its present form through the past occurrence of processes still in operation has come to be known as the doctrine of uniformitarianism. This is a geologic rather than a simply geomorphic doctrine. It is, however, more nearly aimed at actual surficial changes that pertain to landforms than were Werner's notions. The idea championed by Hutton formed the basis of what is now often referred to as process geomorphology. In this area of study, research emphasis is placed on observing what can be accomplished by a contemporary geologic agency such as running water. Later, the role of moving ice, gravity, and wind in the molding of valleys and hillslopes came to be appreciated by study of these phenomena. Uniformitarianism also became the working principle for a growing number of geologic historians, notably William Smith and Sir Charles Lyell, in the 19th century. This was necessary as Lyell argued increasingly that geologic change was incremental and gradual. He needed a longer time scale if this approach was to work, and geologic historians were finding it for him.

Basis of process geomorphology

Gradualism. Lyell's concept of gradualism and accompanying process observation on an expanded time scale resulted in firmly establishing the fact that much could be accomplished by small forces working constantly for long periods. That conclusion is consistent even with present-day thought. Lyell's almost total rejection of any geologic process that was abrupt and suggestive of catastrophe, however, was in itself an extreme posture. Research has shown that both gradual and rapid changes occur.

In the philosophical climate established by Hutton's uniformitarianism and Lyell's gradualism, geomorphologists of the 19th century realized many impressive accomplishments. Most notable among these were the studies of glacial phenomena in Europe by Johann von Charpentier and Louis Agassiz and the investigations of regional denudation in the American West by Grove K. Gilbert and Clarence E. Dutton, which emphasized the work of running water. The findings pertaining to glaciers still stand for the most part, and Gilbert's hydraulic studies laid the

groundwork for modern ideas. Yet, neither he nor Dutton made comprehensive theoretical proposals of terrestrial morphogenesis of a scope that could match those of the aforementioned W.M. Davis.

DAVIS' EROSION CYCLE THEORY AND RELATED CONCEPTS

The geographic cycle. Beginning in 1899, Davis proposed that denudation of the land occurs in what he called "the geographical cycle." According to Davis, this cycle is initiated by an uplift of an area above sea level, followed by a wearing down of the surface through the action of running water and gravity until either the region is worn away (base leveled) or the events are interrupted by renewed uplift (Figure 1). It was further explained that such a cycle of erosion occurs under conditions of a rain-and-rivers environment (what present-day investigators would call a humid climate), which were assumed to reflect the normal climate for the Earth. The fact that Davis dismissed glacial phenomena as accidents of climate and viewed climatic areas as geographically fixed afforded his theory more latitude. Furthermore, Davis proposed the idea of a separate arid geographical cycle in 1905. In all cases, erosive power was presumed to be controlled primarily by slope; hence, the cyclic system was slowed down as the land was leveled and relief and elevation were diminished. The end point of a low-inclination landform was termed a peneplain, and it was said to be locally surmounted by erosionally resistant highs called monadnocks. The peneplain as a whole was presumed to be graded to regional base level (in all likelihood mean sea level) by denudational agencies (*e.g.,* running water), which were supposedly controlled by this datum.

Slope as a denudational influence

The provisions of Davis' erosion cycle run counter to at least half of the 25 constraints on theories of landform evolution listed above. The Davisian erosion cycle theory is hurt by three factors in particular: (1) the presently understood need for continuous isostatic uplift during erosion, (2) the climatic variability displayed by most lands, and (3) the hydraulic behaviour of rivers noted by Gilbert that precludes valley alluviation under normal humid conditions and limits base-level influences over interior slopes.

The notion of an erosion cycle initiated by uplift is still possible within known constraints. Such a cycle is only possible under one particular climatic umbrella, however, and under much more limited geographic and hydrographic circumstances than Davis had assumed. Moreover, the morphological sets of landforms selected by Davis as chronological "mile posts" for his cycle of landform change (*i.e.,* stages of development) have been found to constitute special, generally polygenetic arrays of landscape features that reflect the interplay of several environments and that have little or no sequential time significance.

Davisian dynamic equilibrium. Davis' contribution to the theory of landform evolution also includes the idea of process interruption as a means of accelerating change (rejuvenation) and the notion of process slowing in a late stage of process evolution as energy is consumed. The latter idea comes close to the present-day description of dynamic equilibrium, or attainment of a steady-state (climax) environment and parallels modern thinking on entropy relationships.

Davis proposed his scheme of landscape development stages close on the heels of Charles Darwin's theory of organic evolution, and his designations "youth," "maturity," and "old age" (Figure 1) are blatantly anthropomorphic. Thus, it is quite understandable why they had, at the turn of the century, such appeal and acceptance in spite of their actual lack of chronological significance. Their continued use is less comprehensible.

The geomorphic concepts of Penck and King. The theoretical groundwork laid by Davis for geomorphic evolution was further developed in a rather special fashion in 1924 by Walther Penck of Germany, and subsequently (1953) championed with variations by Lester C. King of South Africa. Both retained some Davisian devices—peneplain, graded stream, and base-level control of erosion surfaces in Penck's case and the latter two in King's. Each thought that tectonic uplift punctuated the erosion cycle by initiating renewed stream incision, and each utilized the concept of parallel retreat of fluvial-structural escarpments to generate plains. King designated the planation process pedimentation, and his end point "pediplains" were surmounted by inselbergs (isolated hills standing above plains, the name being derived from the German term for "island mountains") rather than monadnocks. Because the resulting stair-stepped landscapes (*Treppen,* the German word for "steps") of scarps and flats (Figure 2) were presumed to reflect tectonics and to be correlatable, the term Tectonic Geomorphic School has been applied to its advocates.

The *Treppen* concept

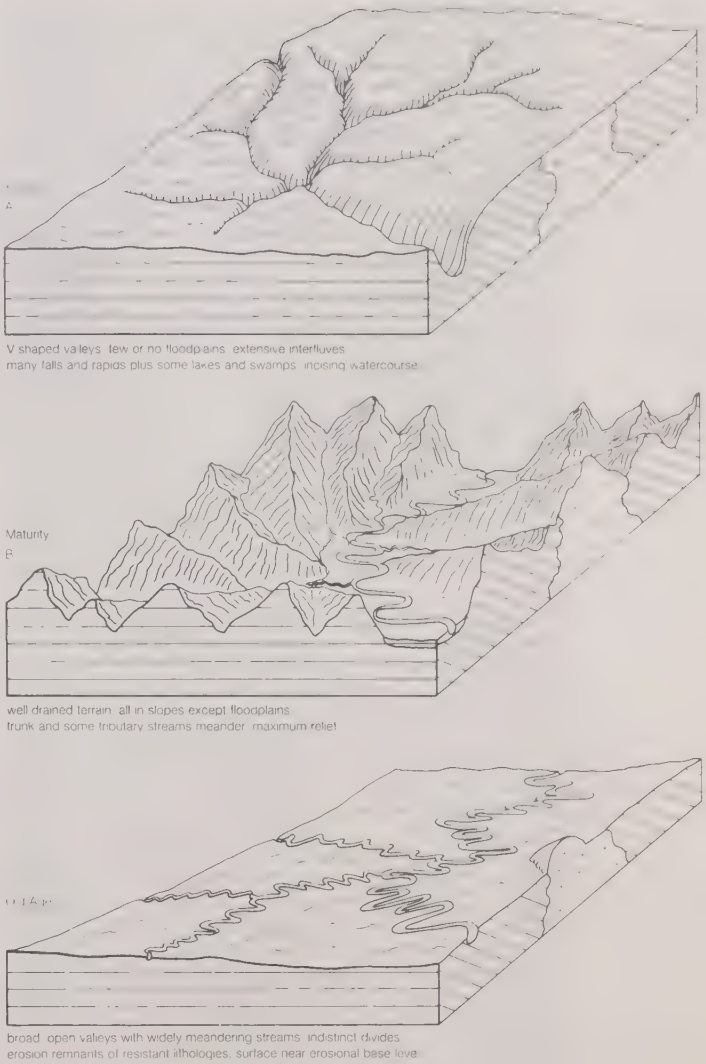

Figure 1: Davis' proposed landscape development states. The morphology shown is not actually time indicative. For example, (A) could be a gully system in soft sediment or a canyon such as the Royal Gorge in Colorado, which is millions of years old. The ridge-ravine topography of (B) would normally develop under humid conditions, but the river meandering on alluvium indicates a prior or extraneous non-humid aggrading mechanism. The riverine plain of (C) implies a complex history of planation and aggradation in a current fluvial mode.

Adapted from H.F. Garner, *The Origin of Landscapes* (1974), Oxford University Press, Inc.

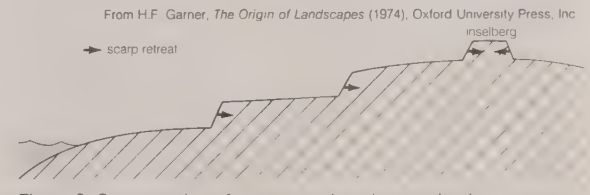

Figure 2: Cross section of an area undergoing erosion by escarpment retreat under Penck's *Treppen* mechanism (see text). Regional base level (± mean sea level) was presumed to provide a limiting downward erosional datum following each episode of uplift marked by stream incision and escarpment development.

The notion of geomorphologists that denudational landforms reflecting tectonic pulses were sufficiently synchronized on a global basis to be correlatable has suffered much from the development of the plate tectonics theory (see PLATE TECTONICS). The separate notion that hillslopes, once developed, retreated laterally to produce a low-inclination surface worthy of a special name (pediment–pediplain) has found more support.

In retrospect, Penck's *Treppen* concept seems to suffer much of the same theoretical damage as Davis' geographical cycle, but it is generally less ingenious. Like Davis, Penck and King made no dynamic use of climatic influences, and in fact the latter went so far as to claim that climate makes no difference. And like Davis, neither King nor Penck acknowledged the isostatic implications for erosion established nearly a century earlier. King suggested that sheetfloods "mold" the surfaces of pediments and depicted sparsely vegetated regions where this might be possible under the label semiarid. More recent work suggests that sheetfloods may be a product, rather than a cause, of the "flat" terrain on which they occur. The so-called molding would appear to be the result of desert stream-flood processes operating to local base levels in the absence of appreciable plant cover, as will be discussed below.

There is an implied landform "chronology" for a geomorphic system tied to intermittent uplift, as suggested by Penck and King, though dating such events is not readily accomplished. Furthermore, King tied his planation method to a regional sea-level erosional datum that the aforementioned constraints throw into question. Perhaps the principal contribution of the Penck–King theoretical ensemble has to do with the concept of lateral escarpment retreat, as opposed to the wearing down of lands favoured by Davis. There are in fact landforms that are widely acknowledged to be pediments. They are planar in form, truncate a wide variety of bedrock types, and can most readily be explained by scarp retreat under non-vegetated conditions. Debate continues about how much or how little moisture best encourages this process. Yet, at least the general nature of the mechanism seems to have been identified (largely by detailed studies in the area of process geomorphology) and the hydraulic constraints established by Gilbert and others seem to be satisfied.

In essence, it has been found that runoff deposits sediment in deserts where its excess transport energy is dissipated by volume loss caused by infiltration and evaporation. Runoff upslope from the depositional base level established by the long-term locus of deposition cannot erode below the resulting deposit (Figure 3). Such overland flow must expend its energy against non-vegetated hillslopes, resulting in their backwearing.

Significance of the pedimentation phenomenon

The pedimentation phenomenon must rank as one of the more astute geomorphic insights, regardless of the fact that the hydraulic and sedimentologic details involved were not established until later. Today, this form of land planation in association with alluvial aggradation in deserts, stream incision that establishes regional drainage networks and augments relief under humid conditions as described by Davis, and glacial scour and deposition as elucidated by Charpentier, Agassiz, and others stand as the three most widely established morphogenetic systems on Earth.

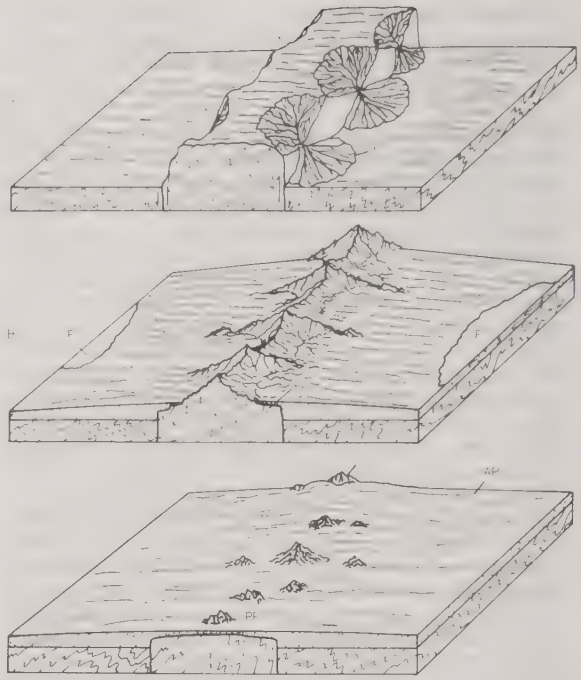

Figure 3: Three-phase block diagram of pedimentation of an upland in a desert. The process of "scarp" retreat and planation is accomplished by sheet wash on non-vegetated surfaces, but it cannot begin until a local base level of erosion–deposition is established. Streams dissecting the upland cannot cut below the level created where deposition of alluvium begins as runoff dissipates. The long-term locus of that deposition established the datum for lateral stream-bank and valley-wall recession at higher elevations. Representative phenomena are designated by letters: alluvial fans (f), marginal pedimentation of horst (Pe), possible playa lake development (P_L), pediplain (PP), inselbergs (I), and aggradation plain (AP).

CLIMATIC MORPHOGENESIS

Recognition of climatic dynamism

Morphogenetic area. Notions that climate plays a major dynamic role in landform evolution only began to emerge about the mid-1900s. At that time the French, particularly Jean Tricart, André Cailleux, and Louis C. Peltier, began to employ the concept of a morphogenetic area—a region in which a particular set of landforms is being generated under a particular climate. Only slowly, however, and mainly from studies in the tropics did it come to be appreciated how extreme the regional climate shifts between arid and humid have been on the different continents. Davis long ago understood how distinctive the geomorphic mechanisms of humid and arid lands were. It was, however, the new evidence of wide geographic mobility for such environments that forced the recognition of the morphogenetic, or geomorphic, system. Such a system is defined as a group of agencies and processes interacting under a particular environment to produce a landscape. Because morphogenetic areas and their systems can displace each other, it follows that they would leave behind relict landforms, soils, deposits, organisms, and so forth.

The discovery of widespread climatic dynamism and the correlative recognition of plate-tectonic phenomena created a whole new theoretical situation for geomorphologists. Not a single theory of regional landform development existing in 1950 accounted for the constraints imposed by the new climatic and tectonic findings in any significant way.

Interactions between geomorphic systems. Climates change and periodically impose one of the foregoing geomorphic systems on the relicts left by one of the others. In addition, areas of each climatic type export matter to adjacent morphogenetic areas and thereby modify the resulting landforms. For example, deserts export dust by eolian means, and the resulting deposits modify soil profiles in downwind regions, as in the eastern United States, or create actual depositional landforms of loess, as in Shansi Province of China on the lee of the Ordos Desert. River systems arising in humid lands develop their drainage networks therein and then may encroach on downslope deserts to create alluvial riverine plains where their flow will not maintain their sediment transport to some distant ocean. Alternatively, rivers form deltas following climate change when their sediment loads and flow are sufficient and the débouché (point of emergence) is protected. Glaciers produce their changes on ice-covered realms and then export their outwash deposits into whatever environment is downslope.

TECTONIC GEOMORPHOLOGY

Tectonic geomorphic systems

In addition to the usual climatic imprints, orogenic tectonism (including volcanism) adds its obvious dimensions of elevation and slope to any surficial environment it encounters. It is now clear that orogenic realms in their early

phases create gravitational opportunities for Earth sculpture that hardly exist elsewhere. The usual mechanisms for concomitantly gradualistic denudation by ice, wind, and running water are set aside in orogenic belts by relatively rapid uplifts of material ranging from nearly unconsolidated sediment to semicoherent but intensely deformed masses of metamorphic and igneous rocks. Under these conditions, masses of rock measured in thousands of cubic kilometres are torn loose by gravity and fall and/or slide, often moving hundreds of kilometres in a "geologic instant" to a lower resting place (in some cases lubricated by subaqueous avenues). The term catastrophic seems most appropriate for an occurrence of this type (see Figure 4C).

Sculpturing of the Earth is thus seen as more than the mere gradual removal of weathered debris by mechanisms under the control of climatic regimes. The Kamchatka Peninsula in the far eastern part of the Soviet Union is said to have more than 100 active volcanoes. Not surprisingly its terrain is dominated by volcanic landforms. The Afar Triangle at the foot of the Red Sea is shaped by newly formed faults that cut unweathered basaltic lava flows on a newly emergent seafloor in an almost totally tectonic landscape. In the Appalachians, south of the glaciated knobs, an ancient mountain system sheathed by thick saprolitic soils on its upper slopes exhibits ridge-ravine topography and may have been in a humid climatic nucleus for 100,000,000 years. Yet, the same region retains water gaps and entrenched meanders that echo drainage patterns established long ago, probably on alluvial cover masses of Early Mesozoic age (roughly 225,000,000 years old) following an arid-to-humid climate change at the end of the Jurassic Period (about 186,000,000 years ago). In the same area, tropical soils and ridge-top lateritic deposits of Georgia and Alabama reflect weathering conditions established 150,000,000 years ago when southeastern North America was still in the tropics before recent northwesterly continental drift.

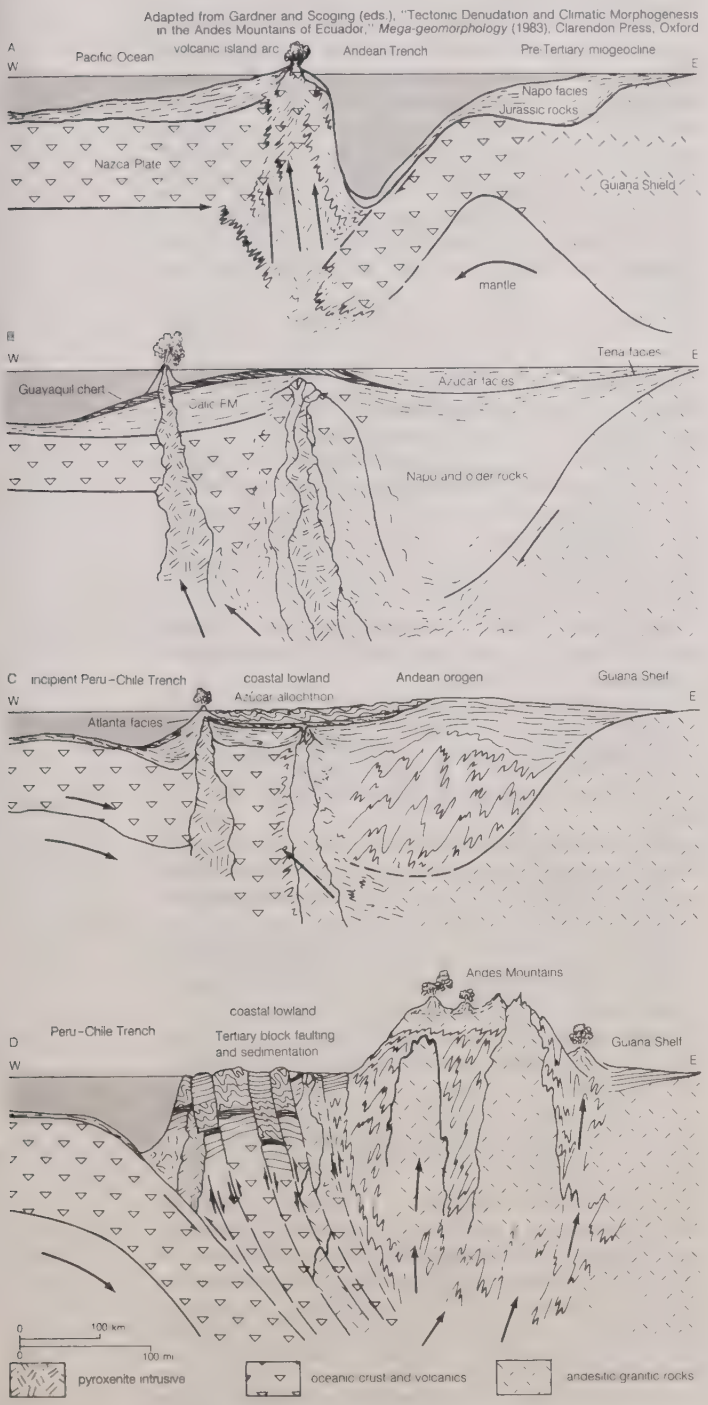

Figure 4: Diagrammatic east–west cross section of the Ecuadorian region in (A) Late Cretaceous, (B) Paleocene, (C) early Eocene, and (D) Oligocene. The Azúcar allochthon reflects tectonic erosion of the rising Andes Mountains. In the early Eocene, about 15,000 to 20,000 cubic kilometres of rock slid at least 250 kilometres in a very brief period of time.

CONSIDERATION OF UNIQUE LANDFORMS AND OTHER DISTINCTIVE TOPOGRAPHIC FEATURES

There are, of course, instances where special types of bedrock combine with particular weathering and erosion regimes to produce unique landforms and landscapes. Best known perhaps are the solutional effects expressed as karst topography. This is most pronounced in limestone terrain, such as that in Kentucky in the southeastern United States and the Karst plateau in Yugoslavia, as well as those in parts of northeast China and on islands like Puerto Rico and Jamaica. In tropical realms where silica is more soluble, similar landforms may develop on other varieties of sedimentary rock or on igneous or metamorphic types, as, for example, quartzite in the isolated plateau remnants of the Venezuelan Guiana Shield. The humid climatic conditions that promote solution production and dripstone formation are readily apparent in such tropical areas.

Karst features

Granitic terrain in several parts of the world also gives rise to a distinctive array of landforms that include domed erosion residuals, often in patterns closely tied to joint spacing in bedrock as noted by the Australian geomorphologist C.R. Twidale. In regions where alternating humid and arid climates or human activity have led to erosional stripping of weathered zones, mammoth boulder piles of exhumed core stones exist. Such features are especially notable on the island of Hong Kong, in southern Brazil, in parts of India and Australia, and in the St. Francois Mountain region of Missouri in the United States.

Theoretical overview

The complexities of terrestrial surface change demand a theoretical overview that is both flexible and multifaceted. Oversimplified, sweeping landscape generalizations that apply to the whole Earth such as the postulates of Davis and King can hardly be employed when dealing with a planet where virtually every geomorphic element constitutes a potential interruption or complication to every other system. Nevertheless, there do seem to be certain kinds of activity that are repeated sporadically in both tectonic and climatic realms. These repetitions encourage the re-creation of particular suites of landforms and could be taken to imply a certain rationality to events. However, they probably are no more rational than eddies in a river that—in a parody of Murphy's Law—develop only where possible.

Matters of geographic and chronological scale also enter into the question of what is indeed geomorphically possible and repeatable. The interplay between density variations in matter and gravity dictates that the Earth's core (once formed) must remain firmly fixed, and so too must the lighter substances that make up the lithosphere. Concentration of the least dense solids in the continents is involved in a complex process now associated with plate tectonics, and it is at this level that a discussion of landform evolution must begin.

Continents as first-order landforms

Although the designers of the plate tectonics theoretical framework did not single out continents as landforms of a special kind, such is one of the basic consequences of that theoretical construct. Continents are first-order landforms, and there seemingly will be only one cycle of continental denudation in the history of the Earth. It began with the earliest concentration of continental lithosphere at the surface. And it presumably will end, as suggested above, when the last endogenic forces (*i.e.*, those within the Earth) expire and gravity and entropy have their way as the internal systems of the planet run down. The details (in the context of the 8,000,000,000- to 10,000,000,000-year span of this cycle) hardly matter, since the results are inevitable—unless, of course, the Sun becomes a nova and disrupts things.

Second-order features on continents consist primarily of mountains and the relatively low-elevation areas that come into existence as the mountains rise. In the context of continental landforms, mountains and the geomorphic systems that act upon them are unique in that the uplift creates an excess of potential energy, one far above that of the remaining land area. Landform evolution in mountains is necessarily skewed by this special kind of excess energy. Davis seemed to sense this in his theorizing, but he did not understand the limits on slope as a denudational influence and the variety of climatic and tectonic factors at work.

OROGENIC AND EPEIROGENIC MORPHOGENESIS

Orogenic geomorphic systems. Such mountain-building systems evolve in the special contexts of type, setting, and style. The principal orogenic varieties recognized are (1) mountains of continent-continent collision type formed by lithospheric plate interaction along continental margins, (2) mountains of the collision type associated with oceanic trenches (sometimes developed along a single continental margin) with an adjacent plate-tectonic subduction system (see below), and (3) rift-type mountains extending into continental interiors where transcurrent faults shear cratons and deform associated sediment veneers or where spreading zones develop to create fault-block (horst-graben) mountainous terrain. Geologic time is sufficient for several orogenic events of each type to have occurred, and different rules apply to the geomorphic evolution of any given type.

Factors in the evolution of mountainous terrains

Mountains of the continent-continent collision type have special attributes that direct their geomorphic evolution. These distinctive characteristics are the following:

(1) The collision creating the mountains incorporates a finite volume of rock that is not augmented following the collision.

(2) The orogenic rock mass is subject to isostatic uplift during denudation; in general, sedimentary rock types are exposed first, followed by crystalline varieties.

(3) The collision that initiates such orogenesis ultimately adds rock to the adjacent craton, and in thickening the adjacent crust often initiates nearby cratonic tilting and/or uplift.

(4) Because such mountains develop between continents and are thus elevated in the midst of a consequent megacontinent (Pangaea in the case of the Appalachians), they are far from oceanic evaporation sources and therefore often undergo initial denudation under arid geomorphic systems in the manner of the present mountains of central Asia.

(5) As the climatic setting of such mountains is largely established tectonically, it may endure in the same climate for scores of millions of years and, as noted in 1901 by the American geomorphologist Douglas W. Johnson, a desert mountain range tends to bury itself in its own waste.

(6) Re-exposure of such mountains to nearby precipitation sources by plate adjustments may result in dramatic climate changes from arid to humid, so that perennial fluvial erosion is widely initiated on a relict arid, alluvial cover mass with resulting transverse drainage by superimposition—one can compare the Appalachian Mountains of North America and the Zagros Mountains of Iran, as described by the American geomorphologist Theodore M. Oberlander in 1965.

(7) Because of their finite initial rock volume, mountains of the continent-continent collision type can be lowered by erosion, somewhat in the manner visualized by Davis. No such structures more than 500,000,000 years old show mountainous relief.

(8) Volcanic landforms are rarely a part of the topography during orogenesis of this mountain type.

Mountains of the collision type associated with oceanic trenches have their own distinct attributes that control evolution. These are as follows:

(1) The merging of a pair of lithospheric plates along a deep-sea trench initiates orogenesis tied to the subduction process (*i.e.*, the sinking of one plate beneath another at convergent plate boundaries).

(2) Rock mass is added to the orogenic belt via subduction as long as the trench remains "operational."

(3) Denudation accompanies uplift and may reduce rock mass in the orogenic system in the long run, but whether the total mass is growing, shrinking, or static depends on the budget established by additions from subduction versus losses from erosion.

(4) Mountainous elevations tend to increase through much of the life of the orogenic system, since rock lost through erosion is generally removed locally and linearly by rivers and glaciers (the Andes exemplify the type bordering a continent, and they appear to be higher now than at any time since they began to form 150,000,000 years ago).

(5) Because mountains of the trench-associated subduction type develop and endure adjacent to an ocean on at least one side, they are subject to climatic variability tied to such factors as latitudinal position, orientation with respect to prevailing wind patterns, ocean surface temperatures, and progressively increasing elevations.

(6) Examples such as the Andes that border a continent can show alternating segments that are highly volcanic.

(7) Andean types also may display highly contrasting denudational systems under a variety of climatic conditions on opposite sides as well as along the length of the range.

(8) Although an erosion cycle resulting in overall lowering of a trench-associated mountain system does not appear viable as long as the trench endures, a complex steady-state mass situation would seem to be one potential development during this time.

(9) Occasionally orogenesis related to trench-continent interaction may extend far inland; the parts of the Andes exhibiting this trait display mechanical rock deformation but little volcanism, and a similar genetic mechanism has been suggested for the Rocky Mountains of North America.

(10) During their early years, the Rocky Mountains displayed volcanic phases accompanied by upthrusting but now seem tectonically quiescent and are apparently experiencing denudational lowering.

Rift-type mountains are primarily of the block-fault variety. They have the following set of special attributes:

(1) Block-fault mountains appear to originate where a spreading ridge of the plate-tectonic type develops.

(2) On continents, the spreading is expressed in high-angle faulting and may be accompanied by volcanism of tholeiitic basalt type.

(3) Rifting may be limited to linear zones, as in the Rift Valley system of East Africa, or may be more broadly expressed, as in the Basin and Range Province of the western United States.

(4) The extent of rifting may be limited to mere surficial fracturing of the continental crust, or it may extend to actual rupturing of a lithospheric plate and renewal of seafloor spreading, as occurred along the Atlantic seaboard of North America at the end of the Jurassic.

(5) Because block-fault mountains are of endogenic origin, they may occur in and experience a variety of denudational environments. The examples from Africa and North America cited above are in settings ranging from arid to humid. The highest such mountains show glacial effects.

For a detailed discussion of mountains and their evolution, see below *Mountains, mountain ranges, and mountain belts.*

Climatically dominated epeirogenic realms. The epeirogenic portions of continents (*i.e.*, those that have escaped orogenesis in the past 500,000,000 years) experience denudation in a situation in which the slope factor, if at all tectonic in origin, is regional in expression and so gentle as to exert little influence beyond giving direction to flowing water or ice. It is these regions that variously exhibit veneers of sedimentary rock largely accumulated in epicontinental seas over the past 500,000,000 years or that expose in shield areas the roots of worn-down mountain systems. In the absence of notable tectonism, it is not surprising to find that morphogenesis on stable cratons is dominated by climate. Vast expanses of cratons situated away from mountain belts either are occupied by temperate and tropical forests and grasslands or are seared by desert heat and wind. Only Antarctica currently sports a continental ice sheet, but both North America and Eurasia show they recently did so as well. It is in these epeirogenic regions that morphogenesis is most significantly punctuated by climate change. With few exceptions, the landforms are polygenetic. Many of the most recent glacial deposits scarcely show the incipient soil development begun under humid conditions only a few thousand years ago. Furthermore, broadly forested, humid regions still exhibit patches of cacti and alluvium left there when they were deserts. Therein, the notable slopes are denudational in origin; the steeper ones were usually developed by stream incision and the more gentle ones commonly were produced by alluviation and/or pedimentation.

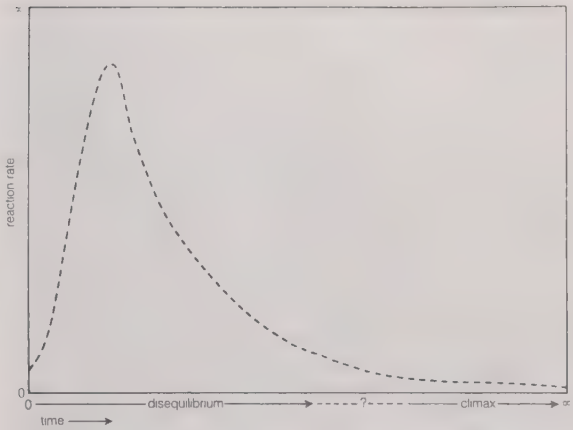

Figure 5: Graph showing the long-term results of a perturbation in a geomorphic system. Where uplift is the cause and creates excess mass subject to gravity and erosion, the disequilibrium phase may endure hundreds of millions of years and the climax, or expression of dynamic equilibrium, would be marked by the elimination of the excess relief and elevation. Where climate change is the cause and leaves relict landforms in a new environment, the disequilibrium continues until the relicts are eliminated or modified into a climax morphology that is in equilibrium with the new system (see text).

From H.F. Garner, "Geomorphic Analogs and Climax Morphogenesis," Arkansas Academy of Science Proceedings (1963)

A UNIFIED LANDFORM THEORY

Viewed in their entirety, the individual concepts that pertain to landform development so far discussed (catastrophism, uniformitarianism, gradualism, erosion cycle, dynamic equilibrium, disequilibrium, geomorphic system, morphogenetic area, tectonic geomorphology, and orogenic and epeirogenic morphogenesis) have to date been treated by theorists as independent conceptual constructs rather than as geomorphic elements of a unified comprehensive theory. There is a close parallel between this situation and the fable of the several blind men who decided what an elephant is by touching only individual parts of the animal. For each of there geomorphic concepts has a measure of validity, but the earliest ideas were formulated on the basis of very incomplete information. When considered in the context of the entire solar system, in which there is a group of planetary geomorphic entities, the theoretical pieces begin to fall into more distinctly rational positions. Although a degree of variability is imposed by planetary location and by early differentiation of cosmic material, randomness in the solar system is incomplete because of the directional factors imposed by gravity, radiation, and increasing entropy. For any given planet, there are two potential geomorphic factors: (1) exogenic impact phenomena from solar debris possibly modified by tidal disruption caused by nearby planetoids, or radiation phenomena tied mainly to the Sun resulting principally in climatic influences and biologic activity, and (2) endogenic phenomena related to internal heating and expressed as tectonism and volcanism, as on the Earth. Morphogenesis occurs in accordance with interaction between planetary subsystems associated with the above factors.

Consideration of factors in the context of the entire solar system

Behaviour of geomorphic systems. Gravity-driven geomorphic systems are potentially cyclical in terms of the elimination of excess relief and elevation. They exhibit activity that graphs in two-phase form—initial disequilibrium when free energy and relief are maximal (and the results are frequently catastrophic), and subsequent dynamic equilibrium where relief and elevation are nearly eliminated and free energy available to do work is so low that change is nearly imperceptible (Figure 5). The latter behaviour is clearly gradualistic. Such systems must be disturbed by outside forces in order for the cycle to be interrupted or reinitiated.

Disequilibrium and dynamic equilibrium

In the solar system the cycle of accretionary, gravity-propelled impact morphogenesis that creates cratered surfaces and high relief is in a distinctly waning phase. Such activity apparently reached a peak within the first 1,000,000,000 years after the planetary system was formed and is not likely to be renewed. Its expression is epitomized by the surface of objects such as the Moon and the planet Mercury, where the near absence of endogenic tectonic forces has left impact effects most intact. On the Earth and a few other planets (or satellites), internal heating propels orogenesis and thereby periodically renews gravity-driven geomorphic cycles. As noted earlier, there will be only one continent-forming cycle in the history of the Earth.

Radiation-driven geomorphic systems are tied to the Sun's nuclear fusion processes and the fluctuations therein. Because of atmosphere and organisms, solar effects are most singularly manifested on the Earth as morphogenetic areas characterized by a particular climate and associated processes. The geomorphic changes in such areas are cyclical largely with respect to the destruction of relict features exposed to the system as the morphogenic areas move and also with respect to the creation of landforms and deposits in morphological equilibrium with the new system. Changes in landforms, deposits, and processes also graph in two phases after the initiation of a system or after a perturbation in one (Figure 5). These landform changes are initially time-indicative, and unless morphogenesis has attained a dynamic equilibrium phase, the partially altered relict features may permit reconstruction of the events of landform evolution.

It will be noted from the above that there is a close relationship between process and form in the dynamic equilibrium phase of radiationally driven geomorphic systems (Figure 6). In morphogenetic areas in states of disequilibrium, form (strongly influenced by relict features) may show little or no conformance to process, which may have just been initiated. Relict features in the process of transformation, such as a desert or a glacial alluvial deposit in a valley being reworked by a perennial stream, thus constitute hybrid features (compare with Davis' mature stream in Figure 1B). The stream valley illustrated has a flat floor unlike that of a late-phase humid valley, as shown in Figure 6, which has a V-shaped cross profile. Furthermore, the "hybrid" stream is not behaving as it would if there were no alluvium, and the alluvium is not the same after the stream has partially reworked it.

Occasionally, the sequence of geomorphic events may conspire to preserve a form that is foreign to the associated geomorphic system and processes. The sinuous paths of entrenched meanders that are cut into bedrock in such regions as the Appalachians express the granular surface and sediment-water volume relations that prevailed when the flow pattern was initiated in the Mesozoic rather than those of the present.

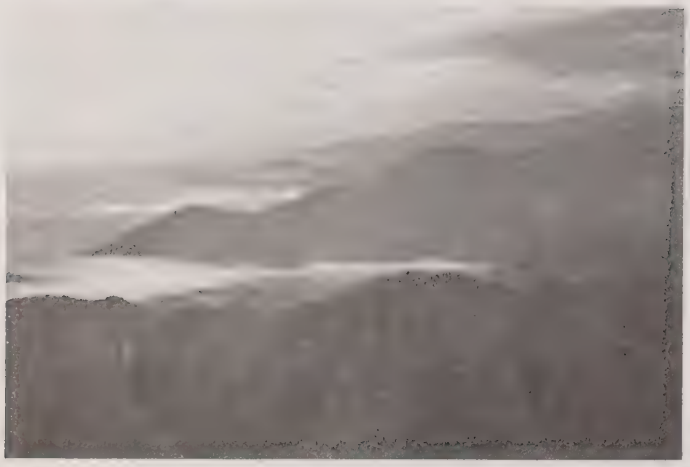

Figure 6: Typical selva (ridge-ravine) topography developed on the forested, humid western spurs of the Andes in central Ecuador. The valleys have V-shaped cross profiles and lack alluvial deposits at their bottoms.
H.F. Garner

The concept of periodic random dominance. On the Earth, gravity- and radiation-driven geomorphic systems interact independently, so that their two types of activity can mingle under conditions of periodic random dominance. Thus, peak energy expenditures engendered by each type of system may or may not coincide geographically. Maximum rates of landform change occur where active orogenesis mingles with changing climates. Minimal change occurs where epeirogenic regions are occupied by morphogenic areas that are in states of dynamic equilibrium. In this arrangement of interacting geomorphic systems, there is clearly a place for both catastrophe and gradualism. There also is a place for cycles of erosion of several kinds and for dynamic equilibrium, either as an end phase of enduring climatic morphogenesis and/or as an end phase of relief and elevation reduction by denudation following orogenesis.

The possibility of polygenetic landforms and landscapes

The concept of periodic random dominance as an aspect of landform evolution carries with it the implication of polygenetic landforms and landscapes where geomorphic system dominance fails to develop. Indeed, dominance becomes the special case because it is dependent on a particular juxtaposition of tectonic and/or climatic elements over a protracted interval in a given area. One estimate places polygenetic landforms over approximately 80 percent of the Earth's land surface. Perhaps 20 percent is experiencing some type of geomorphic system dominance—less than 10 percent if Antarctica is omitted from the calculations.

Process geomorphology and systems equilibria. Details of landform evolution within a given geomorphic system are matters of process behaviour and terrain response. In the context of geomorphic system dominance versus systemic alternation, two general situations exist: (1) those agencies operating in contact with relicts that they are modifying, often quite rapidly, and (2) those in contact with equilibrium features that they have created and have little or no ability to modify further. The principal surficial geomorphic agencies on Earth—wind, running water, glacial ice, and gravity—in any given geomorphic system induce processes that tend to evolve toward a situation of least work. Polygenetic terrain is usually some combination of hillslopes and "flats," and either topographic type may dominate in the latter part of a geomorphic cycle, depending on whether the system tends to generate relief or reduce it.

Natural geomorphic systems operating along the Earth's surface are classified as open, since they are powered by external energy sources. Because the rates of both endogenetic and exogenetic energy input vary, the coordinate agencies experience changes analogous to power surges in an electrical system. Thus rivers receiving excess runoff periodically flood. The atmosphere locally builds up excess heat, and the transfer of this heat is expressed in storms. Glaciers, normally the epitome of slowness, can acquire a mass-energy excess and consequently surge. In all instances, energy available for erosion, transportation, and deposition of sediment varies greatly over time. In addition, the interaction between solids, fluids, and gases results in turbulence, eddy formation, shearing and vortex activity, and periodic local stagnation.

In response to the foregoing situations, process associations within individual geomorphic systems exhibit typical systems phenomena, including "feedback," "threshhold reactions," and evolution toward dynamic equilibrium (least-work) modes. Where a system is periodically perturbed, processes can pass back and forth between disequilibrium and steady-state conditions rather frequently.

The behaviour and apparent process direction of an individual agency may not reflect the evolution of the overall geomorphic system. For example, a 10,000-year-long episode leading to the formation of an alluvial fan may be seen to include numerous incidents of fan-head trenching that are separately destructive but subordinate to depositional events dominating the trend. Similarly, a river such as the Mississippi that is reworking a relict alluvial deposit in a valley may be seen to be depositing gravel on point bars on the insides of bends. The long-term consequence of the river's activity, however, will be to remove the entire alluvial deposit in its path, including the point bars, unless subject to systemic interruption. (Humankind has of course "short-circuited" the natural evolution of the Mississippi and that of many other rivers with engineering modifications.)

From the foregoing, it seems evident that the direction of landform evolution can only be grasped from the study of geomorphic process if the character and role of relict landforms and deposits are clearly understood. This is an obvious complication in the application of Hutton's doctrine of uniformitarianism.

The concept of periodic geomorphic system dominance provides the rational potential end point of landform evolution under a particular set of conditions. Ideally, it may yield either modified or unmodified tectonic landscapes. These in turn may be either orogenic or epeirogenic. Where modified, they may express marine effects and/or glacial, arid, or humid morphogenesis. Antithetically, where more common polygenetic morphogenesis occurs, some mixture of tectonic, marine, or climatic effects is superimposed on the setting, and a hybrid suite of landforms results. (H.F.G.)

TECTONIC LANDFORMS

Effects of tectonic processes

Whereas erosion shapes landforms, their origins lie with tectonic processes that build the major structures of the Earth—mountain belts, mountain ranges, and some individual mountains, as well as plateaus and certain kinds of valleys (rift valleys) and basins. The word tectonic is derived from the Greek word *tekton*, which means "builder." Tectonic processes build landforms mainly by causing the uplift or subsidence of rock material—blocks, layers, or slices of the Earth's crust, molten lavas, and even large masses that include the entire crust and uppermost part of the planet's mantle. In some areas, these processes create and maintain high elevations such as mountains and plateaus. In others, they produce topographic depressions, as exemplified by Death Valley in the western United States, the Dead Sea in the Middle East, or the Turfan Depression in western China. Virtually all areas below sea level have been formed by tectonic processes.

Mountain ranges and plateaus result either from the uplift of the Earth's surface or from the emplacement of volcanic rock onto the surface. Many mountain ranges consist of chains of volcanoes that are made up of rocks derived from depths of tens of kilometres below the sur-

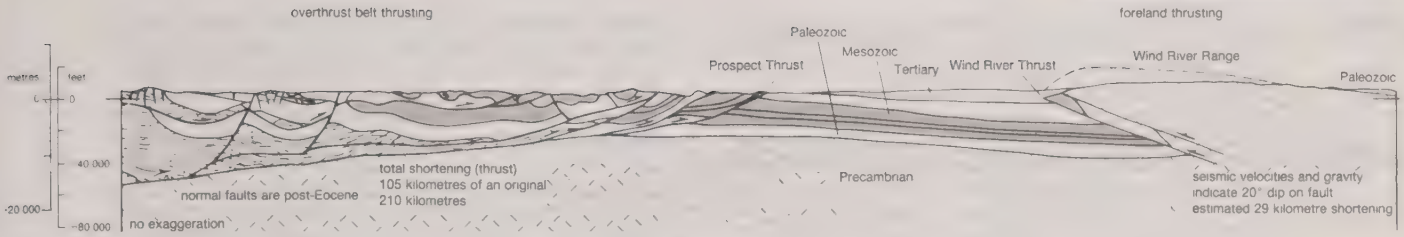

Figure 7: East–west cross section of the fold and thrust belt in eastern Idaho (left) and the block-faulted uplift of the Wind River Range in Wyoming (right).

face. Some plateaus are created by huge outpourings of lavas over vast areas. In addition, the intrusion of molten rock into the crust from below can raise the surface. Many other mountain ranges have been formed by the overthrusting of one terrain or block of crust over an adjacent one, which is another mechanism that uplifts the surface (Figure 7). Similarly, the folding of rocks at the surface creates the ridges and valleys that define some mountain chains (Figure 8). These processes of overthrusting (or underthrusting) and folding result from horizontal forces that cause crustal shortening (in its horizontal dimension) and crustal thickening. Finally, heating and thermal expansion of the outer 100 to 200 kilometres of the Earth can uplift broad areas into either mountain ranges or plateaus.

Similarly, tectonic valleys, basins, and depressions of smaller size can form by the reverse of two of the processes mentioned above. Crustal extension (in its horizontal dimension) and crustal thinning occur where two blocks of crust move apart; a valley or basin forms between such blocks where the intervening segment of crust has been thinned and its top surface subsides (Figure 9). Likewise, subsidence of the Earth's surface can occur by the cooling and the thermal contraction of the outer 100 kilometres of the planet. Plateaus and entire mountain ranges can subside by this mechanism to form large basins in some areas.

Virtually all large-scale landforms are the result of both tectonic processes that built the large differences in elevation and erosional processes that sculpted the relief of such areas into their individual shapes. Thus, it might be said that tectonic processes built the Alps, but erosional processes gave the Matterhorn its unique profile. In all cases, erosion acts to reduce differences in elevation, but when the rate of erosion is not too rapid, landforms created by tectonic processes can persist for hundreds of millions of years after the processes have ceased to operate.

Mountains, mountain ranges, and mountain belts

A mountain belt is a large tract of land, many tens to hundreds of kilometres wide and hundreds to thousands of kilometres long, that stands above the surrounding surface, which usually lies near sea level. Within mountain belts are individual mountain ranges or chains, which extend tens to hundreds of kilometres in length and consist of individual mountains that are connected by ridges and separated by valleys. Within many such belts are plateaus, which stand high but contain little relief. Thus, for example, the Andes constitute a mountain belt that borders the entire west coast of South America; within it are both individual ranges, such as the Cordillera Blanca in which Peru's highest peak, Huascarán, lies, and the high plateau, the Altiplano, in southern Peru and western Bolivia.

GEOMORPHIC CHARACTERISTICS

Mountainous terrains have certain unifying characteristics. Such terrains have higher elevations than do surrounding areas. Moreover, high relief exists within mountain belts and ranges. Individual mountains, mountain ranges, and mountain belts that have been created by different tectonic processes, however, are often characterized by different features.

Volcanic chains

Chains of active volcanoes, such as those occurring at island arcs, are commonly marked by individual high mountains separated by large expanses of low and gentle topography. In some chains, namely those associated with "hot spots" (see below), only the volcanoes at one end of the chain are active. Thus those volcanoes stand high, but with increasing distance away from them erosion has reduced the sizes of volcanic structures to an increasing degree.

The folding of layers of sedimentary rocks with thicknesses of hundreds of metres to a few kilometres often leaves long, parallel ridges and valleys termed fold belts, as, for example, the Valley and Ridge province of Pennsylvania in the eastern United States. The more resistant rocks form ridges, and the valleys are underlain by weaker ones. These fold belts commonly include segments where layers of older rocks have been thrust or pushed up and over younger rocks. Such segments are known as fold and thrust belts. Typically their topography is not as regular as where folding is the most important process, but it is usu-

ally dominated by parallel ridges of resistant rock divided by valleys of weaker rock, as in the eastern flank of the Canadian Rocky Mountains or in the Jura Mountains of France and Switzerland.

Most fold and thrust belts are bounded on one side, or lie parallel to, a belt or terrain of crystalline rocks—metamorphic and igneous rocks that in most cases solidified at depths of several kilometres or more and that are more resistant to erosion than the sedimentary rocks deposited on top of them. These crystalline terrains typically contain the highest peaks in any mountain belt and include the highest belt in the world, the Himalayas, which was formed by the thrusting of crystalline rocks up onto the surface of the Earth. The great heights exist because of the resistance of the rocks to erosion and because the rates of continuing uplift are the highest in these areas. The topography rarely is as regularly oriented as in fold and thrust belts.

Block-fault mountains

In certain areas, blocks or isolated masses of rock have been elevated relative to adjacent areas to form block-fault mountains or ranges. In some places, block-fault ranges with an overall common orientation coalesce to define a mountain belt or chain, but in others the ranges may be isolated.

Block faulting can occur when blocks are thrust, or pushed, over neighbouring valleys, as has occurred in the Rocky Mountains of Colorado, Wyoming, and Utah in the western United States or as is now occurring in the Tien Shan, an east–west range in western China and Central Asia. Within individual ranges, which are usually a few hundred kilometres long and several tens of kilometres wide, crystalline rocks commonly crop out. On a large scale, there is a clear orientation of such ranges, but within them the landforms are controlled more by the whims of erosion than by tectonic processes.

Block faulting also occurs where blocks are pulled apart, causing a subsidence of the intervening valley between diverging blocks. In this case, alternating basins and ranges form. The basins eventually fill with sediment, and the ranges—typically tens of kilometres long and from a few to 20–30 kilometres wide—often tilt, with steep relief on one side and a gentle slope on the other. The uniformity of the gently tilted slope owes its existence to long periods of erosion and deposition before tilting, sometimes with a capping of resistant lava flows on this surface prior to tilting and faulting. Both the Tetons of Wyoming and the Sierra Nevada of California were formed by blocks being tilted up toward the east; major faults allowed the blocks on their east sides to drop steeply down several thousand metres and thereby created steep eastern slopes.

In some areas, a single block or a narrow zone of blocks has subsided between neighbouring blocks or plateaus that moved apart to form a rift valley between them. Mountains with steep inward slopes and gentle outward slopes often form on the margins of rift valleys. Less commonly, large areas that are pulled apart and subside leave between them an elevated block with steep slopes on both sides. An example of this kind of structure, called a horst, is the Ruwenzori in East Africa.

Residual mountains

Finally, in certain areas, including those that once were plateaus or broad uplifted regions, erosion has left what are known as residual mountains. Many such mountains are isolated and not part of any discernible chain, as, for instance, Mount Katahdin in Maine in the northeastern United States. Some entire chains (*e.g.*, the Appalachians in North America or the Urals in Russia), which were formed hundreds of millions of years ago, remain in spite of a long history of erosion. Most residual chains and individual mountains are characterized by low elevations; however, both gentle and precipitous relief can exist, depending on the degree of recent erosion.

TECTONIC PROCESSES THAT CREATE AND DESTROY MOUNTAIN BELTS AND THEIR COMPONENTS

Mountains and mountain belts exist because tectonic processes have created and maintained high elevations in the face of erosion, which works to destroy them. The topography of a mountain belt depends not only on the processes that create the elevated terrain but also on the forces that support this terrain and on the types of processes (erosional or tectonic) that destroy it. In fact, it is necessary to understand the forces that support elevated terrains before considering the other factors involved.

Mechanisms that support elevated terrains. Two properties of rocks contribute to the support of mountains, mountain belts, and plateaus: strength and density. If rocks had no strength, mountains would simply flow away. At a subtler level, the strength of the material beneath mountains can affect the scale of the topography.

In terms of strength, the lithosphere, the thickness of which varies over the face of the Earth from a few to more than 200 kilometres, is much stronger than the underlying layer, the asthenosphere (see PLATE TECTONICS). The strength of the lithosphere is derived from its temperature; thick lithosphere exists because the outer part of the Earth is relatively cold. Cold, thick, and therefore strong lithosphere can support higher mountain ranges than can thin lithosphere, just as thick ice is better able to support larger people than thin ice.

In terms of chemical composition, and therefore density, the Earth's crust is lighter than the underlying mantle. Beneath the oceans, the typical thickness of the crust is only six to seven kilometres. Beneath the continental regions, the average thickness is about 35 kilometres, but it can reach 60 or 70 kilometres beneath high mountain ranges and plateaus. Thus, most ranges and plateaus are buoyed up by thick crustal roots. To some extent the light crust floats on the heavier mantle, as icebergs float on the oceans.

Differences between the crust and lithosphere

It should be noted that the crust and lithosphere are defined by different properties and do not constitute the same layer. Moreover, variations in their thicknesses have different relationships to the overlying topography. Some mountain ranges and plateaus are buoyed up by a thick crust. The lithosphere beneath such areas, however, can be thin, and its strength does not play a significant role in supporting the range or plateau. Other ranges may overlie thick lithospheric plates, which are flexed down by the weight of the mountains. The crust beneath such ranges is likely to be thicker than normal but not as thick as it would be if the lithosphere were thin. Thus, the strength of the lithosphere supports these mountains and maintains the base of the crust at a higher level than it would have if the strong layer were absent. For instance, the Himalayas have been thrust onto the crust of the Indian shield, which is underlain by particularly cold, thick lithosphere that has been flexed down by the weight of the high range. The thickness of the crust is about 55 kilometres beneath the high peaks, which stand more than 8,000 metres high. The thickest crustal segment of 70 kilometres, however, lies farther north beneath the Plateau of Tibet (or Tibetan Plateau), whose altitude is about 4,500 to 5,000 metres but whose lithosphere is much thinner than that beneath the Himalayas. The strong Indian lithosphere helps to support the Himalayas, but the buoyancy of the thick Tibetan crust maintains the high elevation of the plateau.

Tectonic processes that produce high elevations. As noted above, individual mountains, mountain ranges, mountain belts, and plateaus exist because tectonic processes have elevated terrains faster than erosion could destroy them. High elevations are created by three major processes: volcanism, horizontal crustal shortening as manifested by folding and by faulting, and the heating and thermal expansion of large terrains.

Volcanism. Most, but not all, volcanoes consist of material that is thought to have melted in the mantle (at depths of tens of kilometres), which rose through the overlying crust and was erupted onto the surface. To a large extent, the physical characteristics of the erupted material determines the shape and height of a volcano. Material of low density can produce taller mountains than can denser material. Lavas with low viscosity, such as in Hawaii, flow easily and produce gentle slopes, but more viscous lavas mixed with explosively erupted solid blocks of rocks can form steeper volcanic cones, such as Mount Fuji in Japan, Mount Rainier in the northwestern United States, or Mount Kilimanjaro in Africa.

Many volcanoes are built on elevated terrains that owe their existence to the intrusion into the crust of magmas—*i.e.,* molten rock presumably derived from the mantle. The extent to which this process is a major one in mountain belts is controversial. Many belts, such as the Andes, seem to be underlain, at least in part, by solidified magmas, but the volume of the intruded material and its exact source (melting of either the crust or the mantle) remain poorly understood.

Crustal shortening. In most mountain belts, terrains have been elevated as a result of crustal shortening by the thrusting of one block or slice of crust over another and/or by the folding of layers of rock. The topography of mountain ranges and mountain belts depends in part on the amount of displacement on such faults, on the angles at which faults dip, on the degree to which crustal shortening occurs by faulting or by folding, and on the types of rocks that are deformed and exposed to erosion. Most of the differences among mountain belts can be ascribed to some combination of these factors.

Heating and thermal expansion. Rocks, like most materials, expand when they are heated. Some mountain ranges and plateaus are high simply because the crust and upper mantle beneath them are unusually hot. Most broad variations in the topography of the ocean floor, the mid-ocean ridges and rises, are due to horizontal variations in temperature in the outer 100 kilometres of the Earth. Hot areas stand higher—or at shallower depths in the ocean—than cold areas. Many plateaus, such as the Massif Central in south central France or the Ethiopian Plateau, are elevated significantly because the material beneath them has been heated.

Tectonic processes that destroy elevated terrains. Besides erosion, which is the principal agent that destroys mountain belts, two tectonic processes help to reduce high elevations. Horizontal crustal extension and associated crustal thinning can reduce and eliminate crustal roots. When this happens, mountain belts widen and their mean elevation diminishes. Similarly, the cooling and associated thermal contraction of the outer part of the Earth leads to a reduction of the average height of a mountain belt.

Crustal thinning and thermal contraction

MAJOR TYPES OF MOUNTAIN BELTS

Mountain belts differ from one another in various respects, but they also have a number of similarities that enable Earth scientists to group them into certain distinct categories. Each of these categories is characterized by the principal process that created a representative belt. Moreover, within individual belts different tectonic processes can prevail and can be associated with quite different landforms and topography. Thus, for any category there are exceptions and special cases, as well as subdivisions.

Mountain belts associated with volcanism. Volcanoes typically form in any of three tectonic settings. At the axes of the mid-ocean ridge system where lithospheric plates diverge, volcanism is common; yet, high-standing volcanoes (above sea level) rarely develop. At subduction zones where one plate of oceanic lithosphere plunges beneath another plate, long linear or arcuate chains of volcanoes and mountain belts associated with them are the norm. Volcanoes and associated landforms, as well as linear volcanic chains and ridges (*e.g.,* the Hawaiian chain) also can exist far from plate boundaries.

Mid-ocean ridges and rises. Where two lithospheric plates diverge, new material is intruded into the gap between the plates and accreted to each of them as they diverge. The vast majority of volcanic rocks ejected onto the surface of the Earth is erupted at the mid-ocean ridges and rises where this process occurs. Thus, such submarine landforms comprise very long, narrow volcanic centres. Although volcanoes do form as isolated seamounts along the axes of mid-ocean ridges, they constitute only a small fraction of the erupted material. Moreover, areas along the ridges and rises where volcanism is particularly abundant are considered unusual; the excess amount of volcanic activity is generally attributed to "hot spots" in the mantle (see below). Finally, most of the relief that defines the mid-ocean ridges and rises is not due to volcanism at all but rather to thermal expansion, as will be explained below.

Submarine landforms

Volcanic structures along subduction zones. Linear or arcuate belts of volcanoes are commonly associated with subduction zones. Volcanoes typically lie 150 to 200 kilometres landward of deep-sea trenches, such as those that border much of the Pacific Basin. The volcanoes overlie a zone of intense earthquake activity that begins at a shallow depth near such a trench and that dips beneath the volcanoes. They often form islands and define island arcs—arcuate chains of islands such as the Aleutians or the Lesser Antilles (see OCEANS: *Major geologic and geographic features*). Volcanoes usually are spaced a few to several tens of kilometres apart, and single volcanoes commonly define the width of such belts. Elsewhere, as in Japan, in the Cascade chain of the northwestern United States and southwestern Canada, or along much of the Andes, volcanoes have erupted on the margin of a continent. Nearly all features typical of an island arc, including the narrow belt of volcanoes, deep-sea trench, and intense earthquake activity, can be found at such continental margins.

The landscape of island chains of this kind is characteristically dominated by steep volcanic cones topped by small craters, and the relief between these volcanoes is low. A few such volcanoes have undergone massive eruptions and have expelled a large fraction of their interiors, as did Mount St. Helens in the northwestern United States in 1980. In the most intense eruptions of this sort, the remnants of the volcano collapse into the void at its centre, sometimes leaving a caldera (a very large crater with relatively low rims). Examples of such structures include those formed by Krakatoa in Indonesia in 1883 and by Thera (also called Santorin or Santorini) in the Aegean Sea a few thousand years ago.

The lavas erupted at these volcanoes are thought to be derived from the mantle in the wedge of asthenosphere above the lithospheric plate plunging into it. Water carried down in the interstices of the subducted rock and by hydrous minerals to which water is loosely bound chemically is expelled into the wedge of asthenosphere above the subduction zone. The introduction of water reduces the melting temperature of the rocks and allows material in the wedge to melt and rise to the surface.

Landforms associated with hot spot volcanism. Some volcanic phenomena occur at large distances from plate boundaries (for example, on the Hawaiian Islands or at Yellowstone National Park in the western continental United States). Also, as noted above, volcanism is especially intense at some parts of the mid-ocean ridge system (as in Iceland or the Galápagos Islands in the eastern Pacific). Magmas erupted in these settings originate in the asthenosphere, perhaps at depths of several hundred kilometres or more at what are called hot spots in the mantle. Such sources of melting may be due to chemical differences rather than to heat (see VOLCANISM: *Intraplate volcanism*). Active volcanoes are usually localized in a region with dimensions of 100 to 200 kilometres or less.

A chain of extinct volcanoes or volcanic islands (and seamounts), like the Hawaiian chain, or a volcanic ridge, like Walvis Ridge between the islands of Tristan da Cunha and the east coast of Africa, can form where a lithospheric plate moves over a hot spot. The active volcanoes all lie at one end of the chain or ridge, and the ages of the islands or the ridge increase with their distance from those sites of volcanic activity. Older volcanoes are more eroded than younger ones and are often marked only by coral reefs that grow on the eroded and subsiding volcanic island.

Volcanic chains of this kind are not common in conti-

nental regions, in part because most continental masses move slowly over hot spots. Volcanic activity, however, can be particularly abundant when a plate moves so slowly with respect to a hot spot. Moreover, a long duration of volcanism often results in a warming of the lithosphere. This warming causes a localized thermal expansion and consequently a localized upwarping or doming of the Earth's surface, as in the case of the Yellowstone area or the Massif Central in France. The resulting domes cover areas a few to several hundred kilometres in extent, and the mean elevations are rarely as much as 1,000 metres higher than the surrounding regions. Thus, except for the isolated volcanoes that lie on the upwarps, relief is gentle and due largely to erosion.

Formation of domes

Some hot spots are associated with massive eruptions of lava and ash, primarily of basaltic composition, which cover vast areas as extensive as tens or hundreds of square kilometres. Such flood basalts, or traps, buried the Snake River Plain west of Yellowstone a few million years ago, the Columbia River Valley some 20,000,000 years ago, and central India (the Deccan traps) 60,000,000 to 65,000,000 years ago. Flood basalts create a remarkably flat surface that is later dissected into a network of sharply incised valleys (see below *Plateaus*).

Most volcanoes that cannot be ascribed either to a subduction zone or to seafloor spreading at mid-ocean ridges are attributed to hot spots. There are, however, some volcanoes, volcanic fields, and flood basalts that cannot yet be ascribed to hot spots with any certainty. Nevertheless, the landforms associated with such volcanic phenomena resemble those in other settings for which a simple cause can be offered.

Mountain belts associated with crustal shortening. Most mountain belts of the world and nearly all of those in Europe, Asia, and North America have been built by horizontal crustal shortening and associated crustal thickening. The landforms associated with such belts depend on the rates, amounts, and types of crustal deformation that occur and on the types of rocks that are exposed to erosion. To some extent the deformation can be related to different tectonic settings. Large thrusted crystalline terrains and parallel fold and thrust belts are commonly associated with continental collisions in which two separate continents have approached each other and one has been thrust onto the other. Continental collisions are responsible for Alpine-, or Himalayan-, type mountain belts. Fold and thrust belts can also be associated with active continental margins or Andean-type margins, where oceanic lithosphere is subducted into the asthenosphere but where crustal shortening occurs landward of the volcanic arc on the overriding continental plate. Block-faulted ranges commonly form as intracontinental mountain ranges or belts, far from collision zones and subduction zones.

Alpine- (or Himalayan-)type belts. These belts are thought to have been created by the movement of one continent beneath another. In general, a thick layer of light, buoyant continental crust cannot be carried deep into the asthenosphere. Instead, the leading edge of the descending continent is scraped off, and the rest of the continent then plunges beneath the off-scraped slice. Eventually the convergence between the two plates carrying the continents comes to a halt, but usually not before several slices of continental material have been removed from the underthrusting continent and stacked on top of it.

The sedimentary rocks deposited on the continental crust and its margin long before the collision often constitute one or part of one of the off-scraped slices. They commonly are deformed into a fold and thrust belt as the basement under them continues to plunge beneath the overriding plate at the subduction zone. Layers of strong sedimentary rock detach from the underlying basement at weak layers that commonly consist of evaporites (salt, gypsum, or anhydrite) or of shale by a process called décollement (from the French word meaning "ungluing"). The stronger layers of sedimentary rock are then folded into linear, regularly spaced folds—alternating anticlines and synclines—and thrust on top of one another. The Valley and Ridge province of Pennsylvania, which was formed during the collision of Africa and North America near the end of Paleozoic time (about 240,000,000 years ago), is a classic example.

Deformation into fold and thrust belts

Convergence between two lithospheric plates can be rapid in such settings—10 to 100 millimetres per year—and the amount of displacement on the major thrust faults also can be large—tens to more than 100 kilometres. Thus, when a slice of crystalline rock from deep in the crust is scraped off the remainder of the continent and is underthrust by it, much of the slice is uplifted and pushed onto the relatively flat, ancient surface of the intact portion of the continent. Erosion generally removes the sedimentary cover of such slices and leaves expanses of crystalline rocks, as can be seen on Himalayan or Alpine peaks.

Faults along which a slice of continental crust is torn from the rest of the continent and thrust onto it are called ramp overthrusts. When the fault first forms, it dips at 10° to 30° (or more). Slip on this fault (*i.e.*, the movement of one face of the fault relative to the other) brings the leading edge of the off-scraped slice of crust to the surface of the Earth, where it then slides along the surface. The intact continent is flexed down by the weight of the material thrust on top of it. As a consequence, its initially flat surface dips at a very gentle angle of only a few degrees. Accordingly, a ramp overthrust consists of two segments. The first segment, the ramp, dips relatively steeply; slip on it causes uplift of the overriding slice and of the crystalline rocks from deep in the crust to create high relief and the high range. The other segment, which was once the top surface of the continent, has been flexed down and dips at a gentle angle. Slip on it allows the overthrust slice to advance over the rest of the continent, where it plows the sedimentary layers in front of it into folds and smaller overthrusts.

Ramp overthrusts

When a major ramp overthrust is active and the intact continent is flexed down in front of the overriding mountain range, a foreland basin is formed by the flexure (see below *Tectonic basins and rift valleys;* also Figure 10). Foreland basins usually exist as subsurface features that have been filled with debris eroded from the advancing overthrust slice of crust. These deposits, called molasse, can in turn be folded and thrust over one another shortly after they are deposited. Fold and thrust belts in such material, as found at the northern edge of the Alps or at the foot of most of the Himalayas, are often narrow, composed of only one or two parallel folds and faults. The topography associated with them generally consists of low, elongated hills of poorly consolidated sedimentary rock that is easily and rapidly eroded.

Collision zones are thus commonly identified by narrow belts of elevated crystalline terrain and parallel fold and thrust belts. The crystalline terrain has been thrust upward and toward the fold and thrust belt. Deformation is generally confined to shallow depths of only a few kilometres at such belts but penetrates deeply into the Earth beneath the crystalline terrains. The rapid uplift of these resistant rocks creates a high range. A crystalline terrain often exhibits large folds in which the rocks appear to have flowed instead of having been bent. Folds of this sort have formed at depths where the rocks were hot and soft before they reached the relatively cold surface of the Earth. The overthrusting of crystalline terrains onto intact continental crust can occur at rates of tens of millimetres per year, which is rapid for rates of slip on faults, and the crystalline rocks can be uplifted 10 to 20 kilometres by slip on ramp overthrusts.

Andean-type belts. At some continental margins, oceanic lithosphere is subducted. At some of these sites, the landscape is dominated by volcanoes, such as along the Cascades of western North America or in Japan, but at others, such as along much of the Andes of South America, volcanoes constitute only a small or even negligible part of the relief. At Andean-type margins, the crust is typically thicker than normal, and high mountains can exist even in the absence of volcanoes. Some of the thickened crust is due to the intrusion of magma from the mantle, and some to crustal shortening.

Mountains along active continental margins

Oceanic lithosphere is commonly subducted at active continental margins at rates of tens to more than 100 millimetres per year, but crustal shortening within the

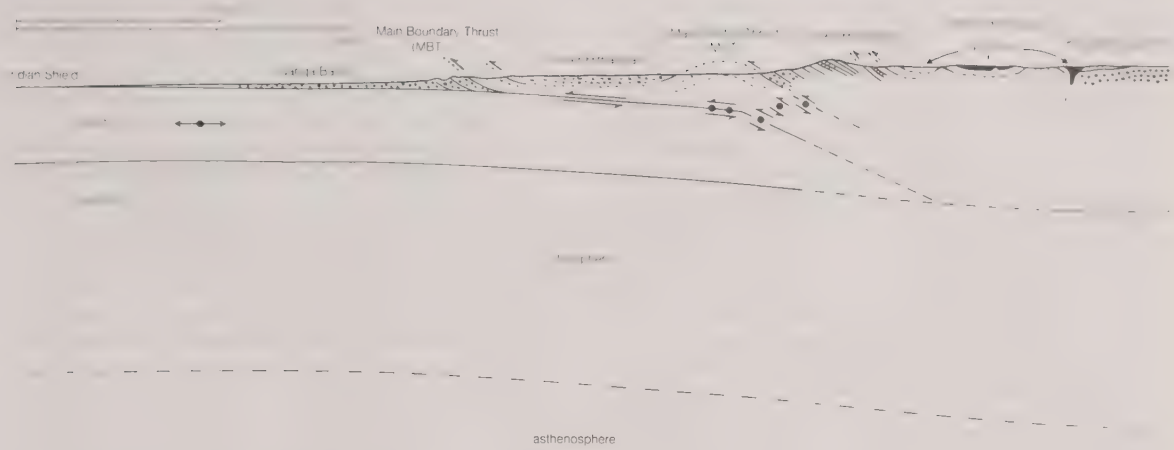

Figure 10: Simplified north–south cross section of the Himalayas, revealing a foreland basin (Ganga Basin), an overthrusting of crystalline terrains onto the Indian Plate, and a steeper thrust fault (a ramp) beneath the Great Himalayas.

Adapted from P. Molnar and W-P. Chen, "Seismicity and Mountain Building," *Mountain Building Processes*, p. 44 (1982) Academic Press, New York

overriding plate typically occurs at rates of only a few millimetres annually. As at continent-continent collision zones, the crustal shortening occurs both by overthrusting of crystalline terrain onto intact continental crust, which in this case lies landward of the volcanic belt, and by the formation of a fold and thrust belt within sedimentary rock lying on the intact continent. The thrusting of crystalline terrain is probably facilitated by a heating and consequent weakening of the rocks near the volcanoes. The presence or absence of a parallel fold and thrust belt depends in part on the presence or absence of thick sedimentary rocks within which detachment of separate layers can take place.

Notwithstanding large variations in topography and in the style of deformation among Andean belts in general, the scales of deformation and uplift are less than those at collision zones. Overthrust crystalline terrains are smaller, and the crystalline rocks themselves have not been thrust up from depths as great as those at collision zones. Much of the Andes, for instance, consists of sedimentary rock that never was buried deeper than a few kilometres and therefore has not been metamorphosed (heated to high temperature or put under high pressure) or at most only has been mildly metamorphosed. Topography in the high parts of the Andes is typically much gentler than in the Himalayas. The most impressive relief is on the eastern flank of the Andes where rivers responding to a wet climate have cut deep canyons.

Fold and thrust belts can be very well developed at Andean margins. The eastern Cordillera of the Bolivian Andes is an extremely wide fold and thrust belt, but only along the eastern third of the cordillera do simple parallel folds control the topography. Farther west, both the greater role of thrust faulting in the evolution of the cordillera and the longer duration of erosion have diminished the role of folding. Except where rivers have cut deep canyons, relief is not exceptionally great. Similarly while oceanic lithosphere was underthrust beneath the west coast of Canada during the Mesozoic Era (248,000,000–65,000,000 years ago), the Canadian shield was underthrust more than 200 kilometres beneath the Canadian Rocky Mountains, with crustal shortening occurring by décollement and by folding and thrust faulting within the sedimentary cover (Figure 11).

Thus Andean-type belts have a narrow belt of volcanoes and often a fold and thrust belt on their landward margin. The volcanoes of some belts are built on a high range that is more of a long, narrow plateau than a mountain range, for relief on it is not necessarily great.

Intracontinental mountain belts. In some regions, mountain belts have been formed by crustal shortening within a continental mass, rather than where two continents have collided. Some 40,000,000 to 80,000,000 years ago, the Rocky Mountains of Colorado, Utah, and Wyoming formed in this way, and today both the Tien Shan and the Atlas Mountains of northwestern Africa are actively forming within a continent. In general, intracontinental mountain belts are characterized by block faulting. Blocks, tens of kilometres wide and hundreds of kilometres long, are uplifted along faults that dip beneath them at angles of 25° to 45°. Because of the displacement on steep faults, crystalline rocks commonly crop out in the mountains. The edges of the ranges can be sharply defined. Fold and thrust belts are not common and are usually narrow where present.

At the edges of such ranges, sedimentary rocks are commonly tilted up, and, where resistant, they can form narrow, sharp-crested ridges called hogbacks that are parallel to the front of the ranges. A particularly prominent hogback lies along the east edge of the Front Range in eastern Colorado.

Intracontinental belts generally consist of elongated block-faulted ranges, which in some cases overlap but are not necessarily parallel to one another. Thus, in parts of the Tien Shan, two or three nearly parallel, sharply bounded ranges are separated from one another by parallel basins that are 10 to 30 kilometres wide. The ranges of this great mountain system are being overthrust onto the basins, and one such basin, the Turfan Depression, has dropped below sea level (see below *Tectonic basins and rift valleys*). In contrast with the parallel ranges in the Tien Shan, the northwest-trending Wind River Range in Wyoming,

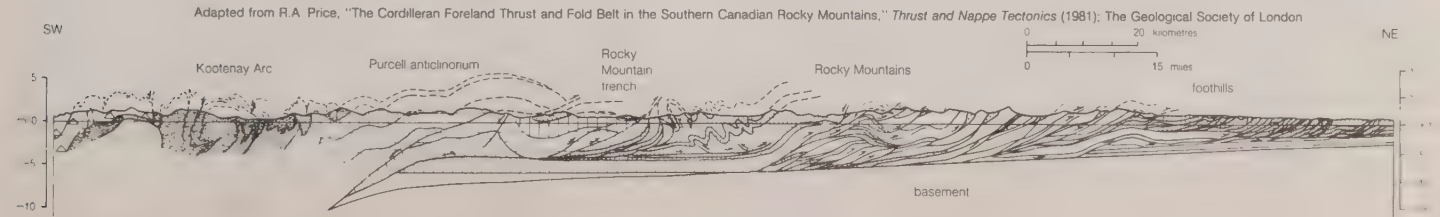

Figure 11: Southwest–northeast cross section of the Canadian Rocky Mountains showing the uplift of crystalline terrains onto the downflexed Canadian shield and the fold and thrust belt on the east side of the range.

the east–west trending Uinta Mountains in Utah, and the north–south trending Front Range in Colorado are all part of the same intracontinental belt, the Rocky Mountains.

MAJOR MOUNTAIN BELTS OF THE WORLD

Most mountains and mountain ranges are parts of mountain belts that have formed where two lithospheric plates have converged and where, in most cases, they continue to converge. In effect, many mountain belts mark the boundaries of lithospheric plates, and these boundaries in turn intersect other such boundaries. Consequently, there exist very long mountain systems where a series of convergent plate boundaries continue from one to the next. A nearly continuous chain of volcanoes and mountain ranges surrounds most of the Pacific Basin (the so-called Circum-Pacific System). A second nearly continuous chain of mountains can be traced from Morocco in North Africa through Europe, then across Turkey and Iran through the Himalayas to Southeast Asia; this chain, the Alpine-Himalayan (or Tethyan) System, has formed where the African, Arabian, and Indian plates have collided with the Eurasian Plate. Nearly all mountain ranges on the Earth can be included in one of these two major systems (Figure 12) and most that cannot are residual mountains, which originated from ancient continental collisions that occurred hundreds of millions of years ago.

Principal mountain systems

The Circum-Pacific System. A nearly continuous chain of volcanoes surrounds the Pacific Ocean. The chain passes along the west coast of North and South America, from the Aleutian Islands to the south of Japan, and from Indonesia to the Tonga Islands, and to New Zealand. The Pacific Basin is underlain by separate lithospheric plates that diverge from one another and that are being subducted beneath the margins of the basin at different rates. This Circum-Pacific chain of volcanoes (often called the Ring of Fire) and the mountain ranges associated with it owe their formation to the repeated subduction of oceanic lithosphere beneath the continents and the islands that surround the Pacific Ocean. Differences among the various segments of the Circum-Pacific chain arise from differences in the histories of subduction of the different plates.

The Andes. The Nazca Plate, which underlies most of the southeastern Pacific, is being subducted beneath most of the west coast of South America at a rapid rate of 80 to 100 millimetres per year. A nearly continuous chain of volcanoes lines the margin of South America, and the world's tallest volcano, Ojos del Salado (6,893 metres), is one of these peaks. The Andean range, however, is more than just a chain of volcanoes, and its highest peak, Mount Aconcagua (6,959 metres), the tallest outside Asia, is not volcanic. Crustal shortening and crustal thickening occur all along the eastern margin of the Andes by the westward underthrusting of the stable areas of Brazil and Argentina beneath the Andes at a rate of a few millimetres per year.

The southern part of the Andes in southern Chile and Argentina consists of a narrow range only 100 to 200 kilometres wide. A chain of volcanoes follows the axis of the range, but crustal thickening due to crustal shortening is a principal cause of the high range, and many of the volcanoes are built on folded and faulted sedimentary rock.

From northern Argentina to northern Peru and Ecuador, the Andes are much wider, with the widest segment across southern Bolivia. There, the mountain belt consists of two parallel ranges, the Cordillera Occidental (or Western Cordillera) and the Cordillera Oriental (or Eastern Cordillera), which surround the high plateau, the Altiplano.

Cordillera Occidental and Cordillera Oriental

The volcanic chain has been constructed on thick crust and forms the Cordillera Occidental. The Brazilian shield has been underthrust beneath the Cordillera Oriental, which comprises the western edge of a wide fold and thrust belt. This fold and thrust belt is marked by north–south trending folds and north–south trending ridges and valleys in northern Argentina and southeastern Bolivia. North of the latitude where the west coast of South America bends, the trend of the Andes, including that of both cordilleras,

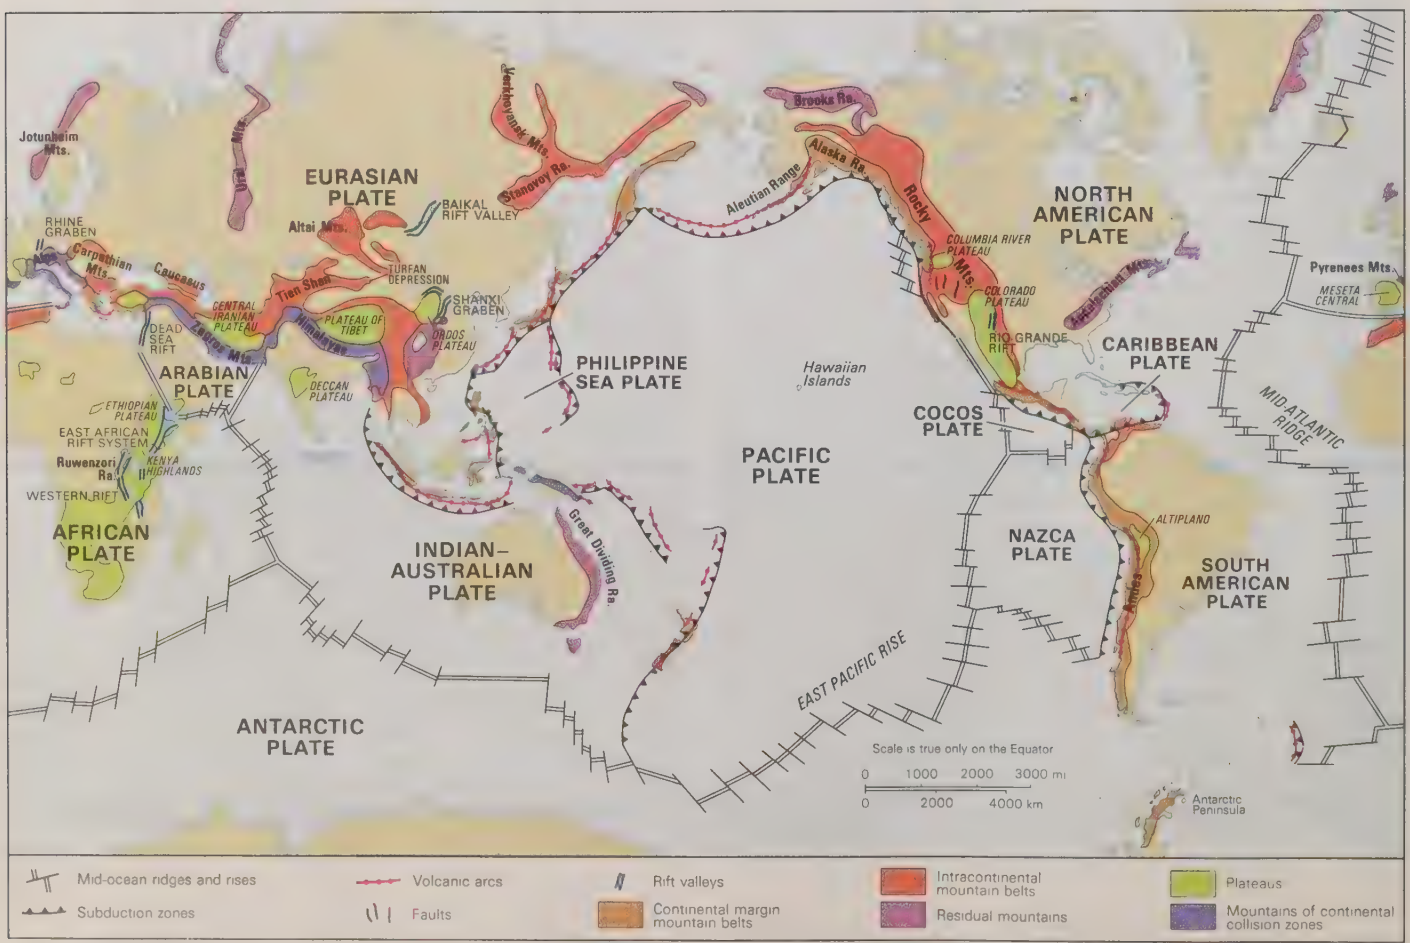

Figure 12: Tectonic map of the world.

is northwesterly parallel to the coast of Peru. The fold and thrust belt east of the Cordillera Oriental is narrower than that farther south but is well defined by a few northwesterly trending ridges and valleys.

Lying between the two cordilleras in northern Argentina, western Bolivia, and southern Peru, the Altiplano stands at an average height of about 3,800 metres. Within it lies Lake Titicaca, the highest navigable lake in the world. The Altiplano is a high arid basin that captures sediment eroded from the eastern and western cordilleras bounding it (see below *Plateaus*). Older rocks that crop out within it have been folded; thus crustal shortening probably has been an important factor in creating the high elevations and the thick crust that underlies this plateau.

In Colombia, the Andean chain diverges into three separate chains, each about 100 kilometres wide. Volcanoes occur in the westernmost chain, but all three have undergone crustal shortening. For example, the easternmost of the three, which continues into Venezuela as the "Venezuelan Andes," is being underthrust from the northwest by the Maracaibo Basin and from the southeast by the Guiana Shield underlying southeastern Venezuela. Thus the Venezuelan Andes are an intracontinental mountain belt.

The divergence of the Andes into three chains in Colombia extends northward. The western chain continues into Panama and through Central America. The central chain continues toward the Caribbean. The Venezuelan Andes intersect an east–west trending chain along the north coast of South America in Venezuela.

The Caribbean chains. The mountain range along the coast of Venezuela is a remnant of a phase when the Caribbean Sea was subducted southward beneath Venezuela and where rocks were folded along east–west axes. Right-lateral strike-slip faulting and rather slow mountain building occur there today, as much by slight vertical displacement on predominantly strike-slip faults as by slow obliquely oriented folding and thrust faulting and associated crustal shortening.

At the eastern end of the Caribbean Sea, the Lesser Antilles—volcanic islands that form a typical island arc—mark a zone where a part of the floor of the North Atlantic Ocean underthrusts that of the Caribbean Sea—namely, the Caribbean Plate. This plate has moved east relative to both North and South America at a rate of 10 to 20 millimetres per year for tens of millions of years. This displacement and the consequent overthrusting of the seafloor to the east are responsible for the volcanic arc that constitutes the Lesser Antilles as well as for the strike-slip displacement occurring in Venezuela.

Mountainous islands of the Caribbean

Most of the major islands that define the northern margin of the Caribbean—Puerto Rico, Hispaniola, Cuba, and Jamaica—are mountainous, and these mountainous terrains, like that in northern Venezuela, are remnants of the period of convergence between North and South America and also of complicated deformation along the ancient margins of the Caribbean Plate. At present, crustal shortening occurs at only a very slow rate, if at all, on these islands.

At the western margin of the Caribbean Plate another small plate, the Cocos Plate, is being underthrust beneath Mexico and Central America. A belt of volcanoes extends from northern Panama to western Mexico, and virtually all of the highest mountains in this belt are volcanic. These volcanoes are built on thickened crust, and crustal shortening has occurred within the Central American Cordillera, but the principal tectonic process that has affected the landscape is volcanism.

The North American Cordillera. A broad mountain belt extends north from Mexico to Alaska, and it reflects both a more diverse and a more complicated history of convergence between lithospheric plates than that presently occurring at the Andes or Central America.

Subduction of oceanic lithosphere presently occurs only beneath two segments of the coast of western North America. The subduction of a small plate, the Juan de Fuca Plate, beneath northern California, Oregon, Washington, and southern British Columbia is responsible for the Cascade chain of volcanoes, which includes Mount St. Helens. The very large Pacific Plate, which underlies most of the northern and western Pacific Basin, moves north-northwest with respect to North America nearly parallel to the coast, and is subducted beneath southern Alaska and the Aleutians. The volcanic chain that forms the Aleutian Islands and continues into the Alaskan peninsula to the Wrangell Mountains is a consequence of this convergence and subduction.

Cascade chain of volcanoes

Most of the North American Cordillera was built during Mesozoic and Early Cenozoic times (between about 170,000,000 and 40,000,000 years ago) when lithospheric plates converged with North America at rapid rates of many tens to more than 100 millimetres per year. The Juan de Fuca Plate is the last remnant of one of these plates. The others have been subducted beneath western North America and have completely disappeared. Thus, in Mesozoic and Early Cenozoic times, an Andean margin similar to that which presently bounds the west coast of South America bounded western North America.

The Coast Ranges of central and northern California, Oregon, and Washington consist of folded and faulted slices of oceanic crust and its overlying sedimentary rocks. Much of the rock that constitutes these mountains was scraped off the oceanic lithosphere at the trench just west of the continent. The Olympic Mountains in northwestern Washington, for instance, consist largely of off-scraped seamounts. The rock of such coastal mountains was intensely deformed and metamorphosed before being elevated to produce the present range. Specifically, the hard basalt that makes up much of the oceanic crust has been metamorphosed into the easily deformed rock serpentinite, which contains the weak, fibrous mineral serpentine. The gentle relief of the Coast Ranges is due in part to the weakness of serpentinite, a characteristic that gives rise to frequent landslides and rapid erosion.

Granite belt of western North America

A belt of granite lies inland and forms a mountainous zone from the axis of Baja California (in Mexico), through southern California, along the Sierra Nevada in the states of California and Nevada, northwestward into Idaho, and then north-northwestward along the western margin of the Canadian Rocky Mountains to Alaska. This granite belt underlay the volcanoes that marked the subduction zone in Mesozoic and Early Cenozoic times. The intrusion of this granite was most intense between 170,000,000 and 70,000,000 years ago during the Mesozoic Era. The Sierra Nevada of California, which contains Mount Whitney, the highest peak in the contiguous United States, is composed almost entirely of this granite.

While subduction of oceanic lithosphere occurred beneath western North America, a major fold and thrust belt developed east of the granitic belt. During Mesozoic time, the Precambrian basement of Canada and North America was underthrust westward at least 200 kilometres beneath the Andean margin, and the sedimentary rocks covering it were folded and thrust onto one another. Although present in the western United States, this fold and thrust belt is most clearly revealed in the Canadian Rockies along the border between the provinces of Alberta and British Columbia, particularly in Banff and Jasper national parks.

In sum, throughout the latter half of the Mesozoic from about 170,000,000 to 65,000,000 years ago, the topography of western North America probably resembled that of western South America: a trench lay offshore; a belt of volcanoes underlain by granitic intrusions marked the western edge of a high range of mountains; and a fold and thrust belt lay east of the range. The tectonic history of western North America is more complicated, however, because during this period fragments of both continents and sub-oceanic plateaus were carried to the subduction zone and collided with North America. Most of the rock now found in westernmost Canada and Alaska consists of separate terrains of rock that were independently accreted to North America and that were subsequently deformed when the next such terrain collided with it. Moreover, tectonic processes occurring during the Cenozoic (since 65,000,000 years ago) have been different from those that occurred earlier and have severely modified the landscape.

Beginning about 70,000,000 to 80,000,000 years ago, the locus of crustal shortening in the United States shifted

The Rocky Mountains of the United States

from the fold and thrust belt, whose remnants now lie along the borders of western Utah and eastern Nevada and of western Wyoming and eastern Idaho, to eastern Utah, Colorado, and central Wyoming. Between about 70,000,000 and 40,000,000 years ago, thrust faulting on the margins of the Front Range in Colorado, the Laramie Mountains and the Wind River Range in Wyoming, and the Uinta Mountains in Utah, among others, allowed the uplift of blocks of Precambrian rock that are now exposed in the cores of these ranges. Together, these intracontinental ranges of block-faulted mountains form most of the Rocky Mountains of the United States.

During roughly the same period, volcanic rocks were erupted and deposited in parts of the Rockies, such as in southwestern Colorado in what are now the San Juan Mountains. The area that now forms the Colorado Plateau, in southern Utah and northern Arizona, underwent only very mild deformation in the form of small faults and folds and apparently lay at relatively low elevation. Sediment derived from the fold and thrust belt to its west and from the Rockies to its north and east was deposited on this relatively stable area. Thus, some 40,000,000 years ago, a high range of mountains lay along the western margin of North America. This range consisted of a volcanic chain along most of its western edge and an eroded fold and thrust belt on its eastern edge. At the latitude of Wyoming, Colorado, and Utah, another belt of mountains, the present-day Rocky Mountains, lay farther east.

The topography of the western United States has been modified extensively by tectonic processes during the last 20,000,000 years. Much of the mountainous terrain of Utah, Nevada, and California underwent large-scale crustal extension, beginning more than 40,000,000 years ago but accelerating about 15,000,000 years ago. The crustal extension approximately doubled the surface area of the region between central Utah and the Sierra Nevada, presumably with a reduction in the mean elevation of the mountains.

The present topography of the Basin and Range Province of North America is a direct manifestation of this crustal extension (see below *Tectonic basins and rift valleys*). The most prominent basins, such as Death Valley and Owens Valley in California, are small rift valleys that were formed during the last few million years. This phase of the crustal extension continues even today, with such basins becoming deeper and the surrounding ranges increasing in height. This condition is readily discernible in the case of Owens Valley and the Sierra Nevada. The occurrence of a major fault on the east side of the Sierras has allowed the valley to drop with respect to the mountain range, which has been tilted up toward the east.

Concurrent with this extension, the uppermost mantle beneath parts of the western United States has become hotter. The considerable height of the Colorado Plateau, for instance, appears to be the result of the warming of the underlying mantle during roughly the past 10,000,000 years. Such mantle heating also seems to have been responsible, at least in part, for the present elevation of much of the North American Cordillera.

The one area where rapid subduction of oceanic lithosphere (more than 50 millimetres per year) has continued is southern Alaska, where the Pacific Plate is being underthrust beneath the coast. The St. Elias Mountains, the tallest in southeastern Alaska and the Yukon, appear to be the direct consequences of this convergence and rapid underthrusting. Deformation of the southern Alaskan crust extends northward several hundred kilometres to the Alaska Range, where the highest mountain in North America, Mount McKinley, is found.

North–south crustal shortening in southern Alaska occurs both by thrust faulting and by strike-slip faulting on nearly vertical, northwesterly trending planes. Mount McKinley lies adjacent to one such major strike-slip fault, the Denali Fault. The rocks that make up Mount McKinley have been displaced several tens of kilometres northwestward relative to the rocks north of the Denali Fault and a few kilometres upward. This small vertical component, compared with the large horizontal component, has created the high peak.

Subduction of the Pacific Plate

Volcanoes and island arcs surrounding the Northwest Pacific Basin. A chain of volcanoes extends from mainland Alaska down the Alaska Peninsula along the Aleutian Islands and then southwestward down the peninsula of Kamchatka in northeastern Siberia and along the Kuril Islands to Japan. The Pacific Plate is being subducted beneath this long volcanic chain. Most of the relief is the result of volcanism. The Aleutians and Kurils are volcanic islands, and for the most part the volcanoes on the continental areas of the Alaska Peninsula, Kamchatka, and Japan are built up from sea level rather than on high ranges, as is the case with the Andes. For instance, Mount Fuji, a symmetrically shaped volcanic cone, rises from a low elevation to more than 4,000 metres.

In the central part of the Japanese island of Honshu, the Circum-Pacific System diverges into two chains. One continues southward along the Izu, Bonin, and Mariana islands. These volcanic islands form island arcs where the Pacific Plate is subducted beneath the floor of the Philippine Sea to the west. Southwest of Honshu, the Ryukyu Islands are another island arc where the Philippine Sea floor is subducted beneath the Yellow Sea.

The Ryukyu island arc ends abruptly at the island of Taiwan, which is not part of the Ryukyu arc. Taiwan is a small mountainous island consisting of folded and thrusted sedimentary rocks on the southeastern margin of the Asian continent. The sedimentary rocks of Taiwan were deposited on that margin under tranquil conditions, much as sedimentary rocks have been deposited on the margins of the Atlantic Ocean. Then, in the last few million years a segment of the Asian continental margin encountered a subduction zone that dipped east-southeast. As that short segment of the margin began to be underthrust, the sedimentary rocks were scraped off its leading edge and thrust back on top of it. Thus, not only the mountains of Taiwan but also virtually the entire island consists of folded and thrust sedimentary rocks that have rapidly piled up on what had been a submerged continental shelf.

A couple of volcanic islands south of Taiwan mark the southward continuation of this subduction zone to Luzon, the large northern island of the Philippines. The mountainous landscape of the Philippine Islands is a consequence both of subduction of the South China Sea floor eastward beneath Luzon and of subduction of the Philippine Sea floor westward beneath the southern Philippine islands. Volcanism and, in Luzon, crustal shortening have built the major mountains.

A major system of island arcs extends across the Indonesian islands of Sumatra and Java and eastward almost to the island of New Guinea and then again eastward along the New Britain, Solomon, and New Hebrides (Vanuatu) chains. Virtually all of the high mountains of the Sunda, or Indonesian, arc are volcanoes, some of which are associated with particularly noteworthy eruptions. In 1883 the massive eruption of the volcano on the island of Krakatoa, in the straits between Java and Sumatra, was followed by a collapse of its caldera, which caused a huge sea wave that was recorded all around the world. The eruption in 1815 of the Tambora Volcano on Sumbawa was perhaps the greatest in recorded history. Debris from this eruption darkened the skies for several months and caused a temporary global cooling that made 1816 "the year without a summer." The Sumbawa volcanic arc is associated with the northward subduction of the Indian Ocean floor beneath Indonesia. Similarly, the volcanic arcs of New Britain, the Solomon and New Hebrides islands, are associated with the northward subduction of the floor of the Solomon Sea and that of the Coral Sea beneath these island arcs.

A high range of mountains forms the backbone of the island of New Guinea between the Sunda and New Britain arcs. Whereas seafloor continues to be subducted beneath these arcs, the northern margin of the Australian continent has encountered the segment of the subduction zone between these arcs. The mountains of New Guinea consist of folded and faulted volcanic and sedimentary rocks. The volcanic rocks include both ancient seafloor and old island arcs that were thrust up and onto the northern

margin of Australia. The sedimentary rock includes a full complement of Paleozoic, Mesozoic, and Cenozoic rock deposited in the tranquil conditions of an ancient continental shelf. Thrust faulting has elevated metamorphic rock to the crest of the high range where glaciers persist even at the Equator, while the sedimentary rock is being deformed in a fold and thrust belt along the southern margin of the range.

East of the New Hebrides Islands, the Circum-Pacific System is defined by the Tonga and Kermadec islands, volcanic islands associated with the westward subduction of the Pacific Plate. The subduction zone continues southward to the North Island of New Zealand, where volcanism is the principal tectonic process that has created mountains and relief. The mountains of the South Island of New Zealand, however, have been produced by different tectonic processes. Whereas the convergence between the Pacific Plate and the seafloor beneath the Tasman Sea manifests itself as subduction of the Pacific Plate at the Tonga-Kermadec-North Island zone, it results in crustal shortening across the South Island. The Southern Alps of New Zealand have resulted from this crustal shortening, which occurs by folding, by thrust faulting, and by vertical components of slip on predominantly strike-slip faults that trend southwest across the northern and western parts of the island. Rapid uplift, possibly as much as 10 millimetres per year, keeps pace with the rapid erosion of the easily eroded schists of the Southern Alps.

The Circum-Pacific System continues southwest of New Zealand along a submarine ridge, the Macquarie Ridge. In short, the Circum-Pacific System consists of a variety of mountain types and ranges where different tectonic processes occurring at different geologic times in the past have shaped the landscape. The grouping of these different belts into this single system is thus only a crude simplification.

The Alpine-Himalayan, or Tethyan, System. The interconnected system of mountain ranges and intermontane plateaus that lies between the stable areas of Africa, Arabia, and India on the south and Europe and Asia on the north owes its existence to the collisions of different continental fragments during the past 100,000,000 years. Some 150,000,000 years ago, India and much of what is now Iran and Afghanistan lay many thousands of kilometres south of their present positions. A vast ocean, called the Tethys Ocean, lay south of Europe and Asia and north of Africa, Arabia, and India. Much of the rock that now forms the mountain system, which includes the Alps and the Himalayas was deposited on the margins of the Tethys Ocean.

Origin

As in the case for the Circum-Pacific System, the grouping of these different mountain ranges into a single system is an oversimplification. The various ranges (and plateaus) of the Alpine-Himalayan System formed at different times, at different rates, and between different lithospheric plates, and consist of different types of rocks.

The easternmost segment of the system begins at the western end of the Sunda island arc and continues into the arcuate chain of mountains that constitute the Himalayas, which contain the highest peaks on Earth. This chain was formed as the Indian subcontinent, a passenger on the same plate that currently underthrusts the Sunda arc, collided with the southern margin of Asia and subsequently penetrated some 2,000 kilometres into the rest of Asia. As the leading edge of India, on which Paleozoic and Mesozoic sedimentary rocks had been deposited, plunged beneath southern Tibet, these rocks were scraped off the subcontinent and thrust back onto its more stable parts. With continued penetration of the Indian subcontinent, slices of the metamorphic basement of its leading edge were scraped off the rest of it and thrust onto one another, so that the rocks of the present-day Himalayan chain consist of slices of India's ancient northern continental margin.

The Himalayan chain

Physiographically, this chain can be subdivided into three parallel belts: the Lesser Himalayas, the Great Himalayas, and the Tethys Himalayas. (Some authorities prefer a subdivision into four belts, the additional one designated the Outer, or Sub-Himalayas.) The Great Himalayas are defined by an arcuate chain of the highest peaks. To the south lie the Lesser Himalayas, a belt about 100 kilometres wide with an average elevation of 1,000 to 2,000 metres that is dissected by the rivers emanating from the Great Himalayas and north of it. To the north, the Tethys Himalayas form the southern edge of the Tibetan Plateau.

The rocks of the Lesser Himalayas consist primarily of mildly metamorphosed sedimentary rock largely of Precambrian age. At present, the remainder of the Indian subcontinent underthrusts the Lesser Himalayas on a very gently dipping thrust fault, so that the rocks forming this belt are sliding over the ancient top surface of India. As a result, the uplift of the Lesser Himalayas seems to be relatively slow.

The rate of uplift in the Himalayas seems to be rapid in two parallel zones: (1) at the very front of the range where the ancient metamorphic and sedimentary rocks of the Lesser Himalayas have been thrust up and onto the young sediments, and (2) beneath the Great Himalayas. The thrust fault that carries the Himalayas onto the intact part of India is a ramp overthrust, with the steep part of the ramp dipping north beneath the Great Himalayas. Slip on this steep part allows the rapid uplift of the Great Himalayas, which in turn creates the high peaks and carries rock from deep in the crust to the Earth's surface.

Most of the constituent rocks of the Great Himalayas are metamorphic; they once constituted the middle and lower crust of India's ancient northern margin but were subsequently scraped off and thrust up onto the surface. The very tops of many of the peaks, however, consist of Paleozoic sedimentary rocks, which dip northward. North of the Great Himalayas, in the Tethys Himalayas, these Paleozoic rocks and the Mesozoic sedimentary rocks deposited on them along the southern edge of the Tethys Ocean have been folded and faulted into east–west ridges.

Geologically, the northern margin of the Himalayas follows the Indus River in the west and the Brahmaputra River (also called Tsang-po or Yarlung Zangbo Jiang) in the east. The last remnants of the Tethys Ocean floor can be found in what some refer to as the Indus-Tsang-po Suture Zone, where a jumble of volcanic and sedimentary rocks have been folded and thrust over one another in a narrow zone parallel to these rivers. North of this suture, a belt of granites forms the backbone of the Trans-Himalayan range. These granites were intruded into the crust of the southern margin of Asia between 120,000,000 and 50,000,000 years ago, when the Tethys Ocean floor was being subducted beneath southern Asia and before India collided with it.

Since India collided with Eurasia, it has penetrated 2,000 kilometres or more into the ancient Eurasian continent. The northern edge of India may have been subducted a few hundred kilometres beneath southern Tibet, but most of its penetration has been absorbed by crustal shortening north of the collision zone. The crust of the Tibetan Plateau appears to have been severely shortened; the thickness of its crust has approximately doubled. Although much of Asia underwent extensive deformation during phases of mountain building in Late Precambrian, Paleozoic, or Mesozoic times, the high altitudes of all of the mountain ranges surrounding the Tibetan Plateau—the Pamir, Karakoram, Kunlun, Nan, Ch'i-lien (Qilian), and Lung-men (Longmen) mountains—have formed since India collided with Eurasia.

In some areas, blocks of crust undeformed since Precambrian time, such as beneath the Takla Makan (or Tarim Basin), have remained in that state, but have been displaced in response to India's penetration. The northward displacement of the Tarim Basin has caused intracontinental crustal shortening in the Tien Shan, the aforementioned east–west trending mountain range with peaks exceeding 7,000 metres in height that lies 1,000 to 2,000 kilometres north of India's northern edge. The Tien Shan was the site of Late-Paleozoic mountain building, but by the time India collided with Eurasia erosion had planed down the ancient Tien Shan to a featureless terrain buried in its own sediment. The present elevation therefore seems to be a consequence of India's penetration into Asia notwithstanding its great distance from India itself.

The Tien Shan

The penetration of India into Eurasia not only has

caused crustal thickening in front of itself, but it also is squeezing parts of Asia eastward out of its northward path. One manifestation of this extrusion of material out of its path is the crustal shortening on the eastern margin of the Tibetan Plateau, where crustal thickening is actively occurring. The eastward displacement of crustal blocks along major strike-slip faults also seems to have caused rift systems to open in a northwest–southeast direction. The Baikal Rift Zone in Siberia and the Shansi Graben in northern China seem to have resulted from the east-southeastward extrusion of material out of India's path. Moreover, crustal thickening in the Tibetan Plateau has ceased, and now east–west extension of the plateau contributes to the eastward extrusion. The plateau is laced with northerly trending rift zones that are bounded by northerly trending tilted, block-faulted mountains. Thus, virtually all of the tectonic landforms of Asia seem to be attributable, directly or indirectly, to India's collision with Eurasia and its subsequent penetration into the continent.

The eastward extrusion has been facilitated by the lack of any major obstacle to the eastward displacement of South China. Minor westward displacement of material also has occurred in Afghanistan, but this process has been blocked by the collision of Arabia with southern Iran and Turkey, where to some extent the same processes have occurred as in eastern Asia.

The Zagros and Bitlis mountains

The Arabian Peninsula, its northeastern edge covered by thick sedimentary rocks, has collided with Iran and Turkey at the Zagros and Bitlis sutures to form the Zagros and Bitlis mountains. Thick layers of salt in the Arabian shield's sedimentary rock have allowed the overlying layers to detach and fold, creating a particularly well-developed fold and thrust belt in the Zagros.

While these overlying sedimentary rocks have become detached and folded, the penetration of the Arabian shield into Iran and Turkey has built plateaus in front of it and mountain ranges on the north sides of the plateaus: the Kopet-Dag and Elburz ranges north of the central Iranian plateau and the Caucasus north of the Anatolian plateau. North–south crustal shortening is the principal process by which these ranges were built, but volcanism has contributed in some cases. Many of the high mountains in this area are volcanoes, including Mount Demavand, which towers over the city of Tehrān, Mount Ararat on the border of Turkey and Armenia where Noah reputedly landed, and Mount Elbrus, the highest peak in the Caucasus. The penetration of the Arabian Peninsula into eastern Turkey also has induced a westward extrusion of Anatolia, the high central part of Turkey. Thus, the same processes active in eastern Asia have affected the landscape of the western portion but only on a smaller scale.

The evolution of the western segment of the Tethyan System is the most complicated, involving more than just a collision of the African continent with parts of Europe. In Early Jurassic time (about 180,000,000 years ago), Africa, which then lay close to Europe, moved southeastward away from it. In doing so, it caused new ocean floor (Tethys) and new continental margins to form. Much of the rock in the Alps, for instance, was deposited on this newly formed margin of southern Europe. Later, during the Cretaceous (about 100,000,000 years ago), the divergence of Africa and Europe ceased, and convergence between them began. Mountain ranges through northern Greece (the Pindus), the Yugoslav region (the Dinaric Alps), Romania, Hungary, the Czech Republic, and Slovakia (the Carpathians), and Austria, Switzerland, France, and Italy (the Alps) all formed as the Italian peninsula—a promontory on the African continent—moved first north-northeast toward Europe at 20 to 30 millimetres per year and later northwest at a slower rate of about 10 millimetres per year. The change in the direction of motion and the irregular shape of this promontory are two reasons that the tectonic evolutions of the different ranges of Europe are very different from each other. This is unlike the situation of the Himalayas, where the history of the belt is similar throughout the 2,500-kilometre-long range.

The western Alps

The best-studied of these ranges is the western Alps in Switzerland and France. The western end of the Tethys Ocean floor was subducted beneath northern Italy until about 45,000,000 to 35,000,000 years ago. At that time, southern Europe and northern Italy collided. As the southern margin of Europe began to be subducted beneath northern Italy, the sedimentary cover deposited on the European margin of the Tethys Ocean was detached and scraped off the margin. Thick layers of relatively strong sedimentary rock (*e.g.*, limestone and sandstone) that had been deposited on weak layers of salt (and in some cases shale) became detached and folded into huge nappes—enormous, flat layers of rock that seem to have been folded and sometimes dragged over one another like sheets of cloth pushed over a table or bed.

As northern Italy continued to override the coast of southern Europe, it not only pushed the sedimentary cover farther onto the European landmass, but it also scraped up bits and pieces of the deeper metamorphic rocks of Europe's basement. Moreover, as the crust thickened, the increase in pressure and temperature metamorphosed the deeply buried rocks. Although there are exceptions, the northern and western parts of the Alps thus are dominated by folded, unmetamorphosed sedimentary rock, and the southern part consists largely of metamorphic rock.

As Europe was flexed down under the weight of the Alps thrust onto it, a foreland basin (see below) formed just north of the Alps: the Molasse Basin of northern Switzerland and southern Germany. Continental convergence in the past 10,000,000 years has caused folding and thrusting in the Jura Mountains of northwest Switzerland and France, and displacement on ramp overthrusts beneath the front of the Alps has elevated several crystalline massifs: the Belledonne and Mont Blanc massifs in France and the Aare (or Aar) and Gotthard massifs in Switzerland. Moreover, with the elevation of the Alps above the Po plain of northern Italy, a southward overthrusting has carried the southern part of the Alps back onto the basin there as the Italian promontory has continued to penetrate into the rest of Europe.

The Apennines

The Apennines, which form the backbone of the Italian peninsula, were built by the folding and faulting of sedimentary rock deposited on the peninsula (Figure 13). The deformation in a direction nearly perpendicular to that of the Alps was due in part to a phase of the northeastward movement of Italy toward the Adriatic coast of the Balkan Peninsula and also to the rotation of Corsica and Sardinia away from southern France and toward Italy. Thus, while the crust of the Alps was being shortened in its north–south or northwest–southeast dimension, that of the Apennines was being shortened in its northeast–southwest dimension.

While the Alps, the Apennines, and the ranges of eastern Europe were being built, different processes created mountain ranges in parts of western Europe and destroyed others in eastern Europe. For instance, while the last remnant of the Tethys Ocean, the eastern Mediterranean Sea, continues to be subducted beneath Greece and Turkey, north–south crustal extension and associated crustal thinning occurs in the Aegean area and western Turkey. This crustal thinning has already lowered the surface of what may have been a high range or plateau to below the level of the Aegean Sea and is reducing the average elevation of western Turkey.

In contrast, the western Mediterranean Sea—between Italy, Spain, and North Africa—was formed during the past 30,000,000 years and is not a remnant of the Tethys Ocean. Since that time and concurrently with the subduction of the Tethys lithosphere beneath southern Italy, Greece, and Turkey, fragments of crust have separated from southern Europe. As these fragments drifted across the ancient westernmost end of the Tethys Ocean, they opened the new western Mediterranean basin behind them.

The collisions of these fragments with parts of Italy and Africa have contributed to the building of mountain ranges in these areas. Corsica and Sardinia swung out from southern France, and the eastern margin of Corsica, which lies below sea level, collided with Italy. The Calabrian peninsula of southern Italy once lay against Sardinia, but its southward drift opened the Tyrrhenian Sea. The volcanoes of Italy, including Mount Vesuvius near Naples and Mount Etna on Sicily, were formed as a result of the sub-

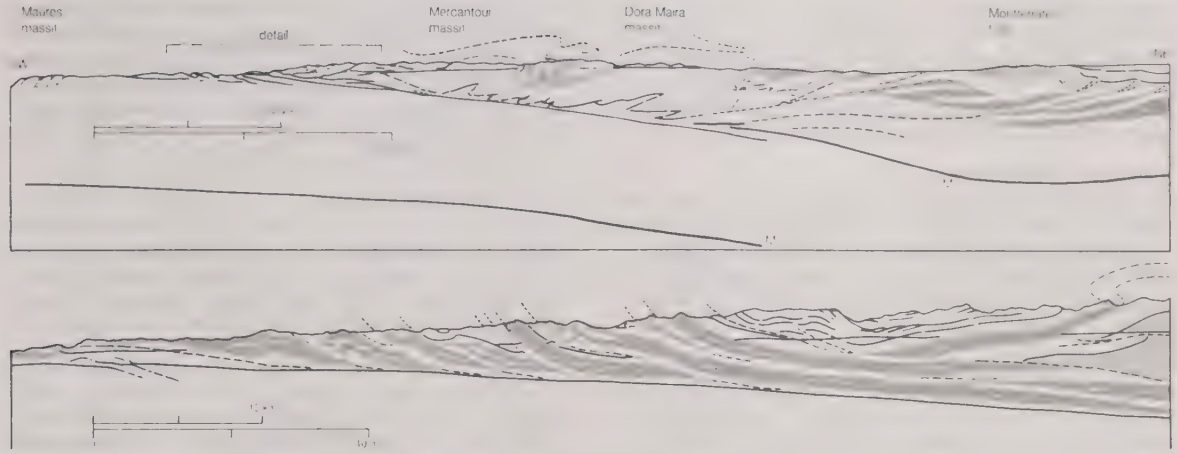

Figure 13: (Top) Small-scale cross section of the Maritime Alps and northern Apennines. (Bottom) Large-scale cross section of a portion of the Alps. Folding and faulting are apparent at both shallow and deep levels.

duction of the ancient oceanic lithosphere of the Tethys beneath the Calabrian arc, which only recently collided with the rest of Sicily and the southern part of the Italian peninsula. Small fragments farther west collided with North Africa, causing crustal shortening and mountain building across northern Tunisia, Algeria, and Morocco.

The Pyrenees

The convergence of another small fragment with Europe built the Pyrenees. The Iberian Peninsula lay against the western margin of France until about 90,000,000 or 100,000,000 years ago, when it began to rotate into its present position and opened the Bay of Biscay behind it. As the peninsula moved toward southern France, a combination of crustal shortening and strike-slip deformation along the Pyrenees built the narrow range that separates Spain and France.

Residual mountain ranges and thermally uplifted belts. Although isolated mountains and mountainous terrains exist on all continents, most mountain belts not part of either the Circum-Pacific or the Alpine-Himalayan systems either are composed of residual mountains or owe their existences to localized thermally induced uplifts. Most such linear belts are residual ranges. The Appalachians in the eastern United States, for example, emerged as a result of a collision between Africa and North America in Late Paleozoic time before the present Atlantic Ocean formed. The well-developed Valley and Ridge province in the states of Pennsylvania, West Virginia, Virginia, and Kentucky has been eroded, but strong layers remain and define the ridges that once were limbs of folded layers. Similarly, the Ural Mountains were formed by the collision of Europe and Siberia in Late Paleozoic time. Much of the mountainous terrain in northeast Siberia was formed by collisions of continental fragments with the rest of Siberia in Mesozoic time.

Some high areas follow old mountain belts, but the present elevations are the result of recent uplift due to the heating of the lithosphere and to its thermal expansion. Strictly speaking, these belts are not residual mountain ranges. The mountainous topography of Norway and northern Sweden, for instance, follows an Early Paleozoic belt that marks the zone where Europe and North America (including Greenland) collided more than 400,000,000 years ago, long before the present Atlantic Ocean formed. The present-day topography, however, probably exists because this area was heated when Greenland was rifted away from Europe some 55,000,000 years ago when the North Atlantic Ocean began to form. Similarly, the mountains of eastern Australia, including the Snowy Mountains that contain the continent's highest peak, follow a Paleozoic belt; yet, the present topography seems to be the result of the warming of the lithosphere both when New Zealand separated from the east coast of Australia some 80,000,000 to 90,000,000 years ago and again when Australia drifted over a hot spot in the asthenosphere tens of millions of years ago.

The Snowy Mountains of Australia

Except for the chain of mountains across North Africa, virtually all mountains and high terrains on that continent and on Antarctica result from thermal processes. The high margins of the Red Sea and the Gulf of Aden on both Africa and Arabia are due to the heating of the lithosphere that occurred when these narrow bodies of water began to open 20,000,000–40,000,000 years ago and to the existence of a hot spot in the asthenosphere beneath the Ethiopian Plateau. Most of the high plateaus of central and southern Africa, such as the Ahaggar, formed because of hot spots beneath them. The same can be said of the high plateau that surrounds the East African Rift System and of the high volcanoes, such as Mount Kilimanjaro and Mount Kenya, built on that plateau. Similarly, the Transantarctic Mountains probably are high because of recent heating of the lithosphere beneath them. At the end of the range are two volcanoes, Mount Erebus and Mount Terror, which probably owe their existence to a hot spot beneath them.

Most of the highlands of continents that are not characterized by chains of mountains have resulted from a heating of the lithosphere. The majority of them, however, are better described as plateaus than mountain ranges.

Plateaus

Plateaus are expanses of terrain that stand at higher elevation than surrounding terrain, but they differ from mountain ranges in that they are remarkably flat. Some plateaus, like the Altiplano in southern Peru and western Bolivia, are integral parts of mountain belts. Others, such as the Colorado Plateau (across which the Colorado River has cut the Grand Canyon), were produced by processes very different from those that built neighbouring mountain ranges. Some plateaus, as, for example, the Deccan Plateau of central India, occur far from mountain ranges. The differences among plateaus can be ascribed to the different geologic processes that have created them.

GEOMORPHIC CHARACTERISTICS

The high flat surface that defines a plateau can continue for hundreds or even thousands of kilometres, as in the case of the Tibetan Plateau. In spite of the paucity of roads, one can drive over most of this plateau, where elevations exceed 4,500 metres, and encounter less relief than in some major cities of the world (*e.g.*, San Francisco or Rio de Janeiro). Although ranges of hills and mountains rise above the rest of the plateau, their topography, too, is rather gentle.

Dissection by rivers and deep canyons

Plateaus dissected by rivers have remarkably uniform maximum elevations, but their surfaces can be interrupted by deep canyons. In the case of some regions described as plateaus, the surface is so dissected that one does not see any flat terrain. Instead, such a plateau is defined by a uniform elevation of the highest ridges and mountains.

The eastern part of the Tibetan Plateau, which constitutes the headwaters of many of the great rivers of Asia (*e.g.*, Huang Ho, Yangtze, Mekong, Salween, and Irrawaddy), is dissected into deep canyons separated by narrow, steep ridges; the high uniform elevation that characterizes plateaus is only barely discernible in this area.

FORMATIVE PROCESSES

The formation of a plateau requires one of the same three types of tectonic processes that create mountain ranges—volcanism, crustal shortening, and thermal expansion (see above). The simplest of these is thermal expansion of the lithosphere (or the replacement of cold mantle lithosphere by hot asthenosphere).

When the lithosphere underlying a broad area is heated rapidly—*e.g.*, by an upwelling of hot material in the underlying asthenosphere—the consequent warming and thermal expansion of the uppermost mantle causes an uplift of the overlying surface. If the uplifted surface had originally been low and without prominent relief, it is likely to remain relatively flat when uplifted to a relatively uniform elevation. The high plateaus of East Africa and Ethiopia were formed this way. As in parts of Africa, plateaus of this sort can be associated with volcanism and with rift valleys, but these features are not universal. Most of the high plateau in East Africa that holds Lake Victoria does not contain volcanic rock and is cut only by small, minor rift valleys.

Where the uplifted surface lay at a low elevation for a very long time and was covered by resistant sedimentary rock, the flatness of the plateau can be particularly marked. The rock underlying the Colorado Plateau has undergone only very mild deformation since Precambrian time, and layers of very resistant limestone and sandstone deposited during the Paleozoic form its top surface in many areas. The warming of the underlying lithosphere in late Cenozoic time caused this area to rise to its present elevation, and those resistant Paleozoic formations define the surfaces that make the remarkably flat horizons at the Grand Canyon (see Figure 17 below).

The Colorado Plateau

The great heights of some plateaus, such as the Tibetan Plateau or the Altiplano, are due to crustal shortening. The geologic structure of plateaus of this kind is entirely different from that of the Colorado Plateau, for instance. Crustal shortening and crustal thickening, as described above, have created high mountains along what are now the margins of such plateaus. In most mountain ranges, streams and rivers transport eroded material from the mountains to the neighbouring plains. When drainage is internal and streams and rivers deposit their debris in the valleys between mountains, however, a plateau can form. The surface of this sort of plateau is defined by very flat, broad valleys surrounded by eroded hills and mountains. The rocks that make up the mountains and the basement of the valleys are often strongly deformed, but the young sediment deposited in the valleys usually lies flat. These plateaus generally survive erosion only in dry climates where erosion is slow. In many cases, the valleys, or basins, are occupied by flat dry lake beds. Thus, plateaus built by crustal shortening are really mountain ranges buried in their own debris.

Lava plateaus

A third type of plateau can form where extensive lava flows (called flood basalts or traps) and volcanic ash bury preexisting terrain, as exemplified by the Columbia Plateau in the northwestern United States. The volcanism involved in such situations is commonly associated with hot spots. The lavas and ash are generally carried long distances from their sources, so that the topography is not dominated by volcanoes or volcanic centres. The thickness of the volcanic rock can be tens to even hundreds of metres, and the top surface of flood basalts is typically very flat but often with sharply incised canyons and valleys.

The separation of plateaus into the above three types is not always easy because two or even all three of the processes involved frequently operate simultaneously. For instance, where the uppermost mantle is particularly hot, volcanism is common. The Ethiopia Plateau, on which Precambrian rocks crop out, stands high because the underlying lithosphere has been heated; however, Cenozoic volcanic rocks cover much of the plateau, especially those areas that are the flattest. Although the scale is different, there are active volcanoes and young lavas covering some broad basins on the northern part of the Tibetan Plateau. All three processes—thermal expansion, crustal shortening, and volcanism—may have contributed to the high, flat elevation of at least part of this plateau.

GEOGRAPHIC DISTRIBUTION

Plateaus of one type or another can be found on most continents. Those caused by thermal expansion of the lithosphere are usually associated with hot spots. The Yellowstone Plateau in the United States, the Massif Central in France, and the Ethiopian Plateau in Africa are prominent examples. Most hot spots are associated with the upwelling of hot material in the asthenosphere, and this hot upwelling not only heats the overlying lithosphere and melts holes through it to produce volcanoes but also uplifts the lithosphere. The relationship of such plateaus to hot spots insures both a wide distribution of plateaus and an absence of belts of plateaus or of interrelated plateaus.

Some plateaus, like the Colorado Plateau, the Ordos Plateau in northern China, or the East African Highlands, do not seem to be related to hot spots or to vigorous upwelling in the asthenosphere, but appear to be underlain by unusually hot material. The reason for localized heating beneath such areas is poorly understood, and thus an explanation for the distribution of plateaus of this type is not known.

Plateaus that were formed by crustal shortening and internal drainage lie within major mountain belts and generally in arid climates. They can be found in North Africa, Turkey, Iran, and Tibet, where the African, Arabian, and Indian continental masses have collided with the Eurasian continent. The Altiplano lies between the Cordillera Occidental composed of volcanoes and the Cordillera Oriental beneath which the Brazilian shield is being thrust. All these areas have undergone crustal shortening during Cenozoic time, and in each case the surface of the plateau includes both strongly deformed pre-Cenozoic rocks and very young, flat-lying sediment.

The Altiplano

There are some plateaus whose origin is not known. Those of the Iberian Peninsula and north-central Mexico exhibit a topography that is largely high and relatively flat. Crustal shortening clearly occurred in Mexico during the Late Cretaceous and Early Cenozoic (between 100,000,000 and 50,000,000 years ago) and in some parts of Spain during the Cenozoic, but the high elevations in either case do not seem to be supported by thick crust. These areas are probably underlain by a hot uppermost mantle, but proof of this is still lacking.

Volcanic plateaus are commonly associated with eruptions that occurred during the Cenozoic or Mesozoic. Eruptions on the scale needed to produce volcanic plateaus are rare, and none seems to have taken place in recent time. The volcanic eruptions that produce lava plateaus tend to be associated with hot spots. For example, the basalts of the Deccan traps, which cover the Deccan Plateau in India, were erupted 60,000,000 to 65,000,000 years ago when India lay in the Southern Hemisphere, probably over the same hot spot that presently underlies the volcanic island of Réunion. The Serra Geral basalts that cap a plateau of the same name on the Atlantic coast of Brazil were erupted some 135,000,000 years ago before Africa and South America separated from each other and when the future continental margins overlay the hot spot now beneath the volcanic island of Tristan da Cunha in the South Atlantic Ocean. In North America, the Columbia River basalts may have been ejected over the same hot spot that underlies the Yellowstone area today. Lava plateaus of the scale of these three are not common features on the Earth.

Tectonic basins and rift valleys

GEOMORPHIC CHARACTERISTICS

Most tectonic basins and valleys, including rift valleys, are characterized by relatively steep, mountainous sides and flat floors. The steep sides are created by displacement on

faults such that the valley floor moves down relative to the surrounding margins, or, conversely, the margins move up relative to the floor. Differences in the elevations of valley floors and surrounding mountains or plateaus range from only several hundred metres to more than 2,000 metres in major rift valleys. The widths of tectonic valleys and basins vary from as little as 10 kilometres to more than 100 kilometres. Their lengths typically are hundreds of kilometres, but range from a few tens to thousands of kilometres.

The vast majority of tectonic basins and valleys is produced by an extension of the Earth's crust and the subsequent dropping of a block of crust into the space created by the divergence of large crustal blocks or lithospheric plates. The extension of the brittle crust causes it to fracture, and as the adjoining crustal blocks or plates move apart, a smaller block slides down into the resulting gap. The down-dropping of this block between the surrounding fault blocks, which commonly rise during an episode of crustal extension, creates a rift valley or tectonic basin. The geologic term for this type of tectonic depression is "graben," the German word for "ditch" or "trough."

Graben

Tectonic depressions also can be produced by horizontal compression of the crust—*i.e.,* by crustal shortening. Two types of compressional tectonic valleys and basins can be recognized: ramp valleys and foreland basins. A ramp valley is analogous to a rift valley but is formed by the margins of the valley being pushed over its floor. A foreland basin, on the other hand, results from a gentle downward bending or flexing of the entire lithosphere.

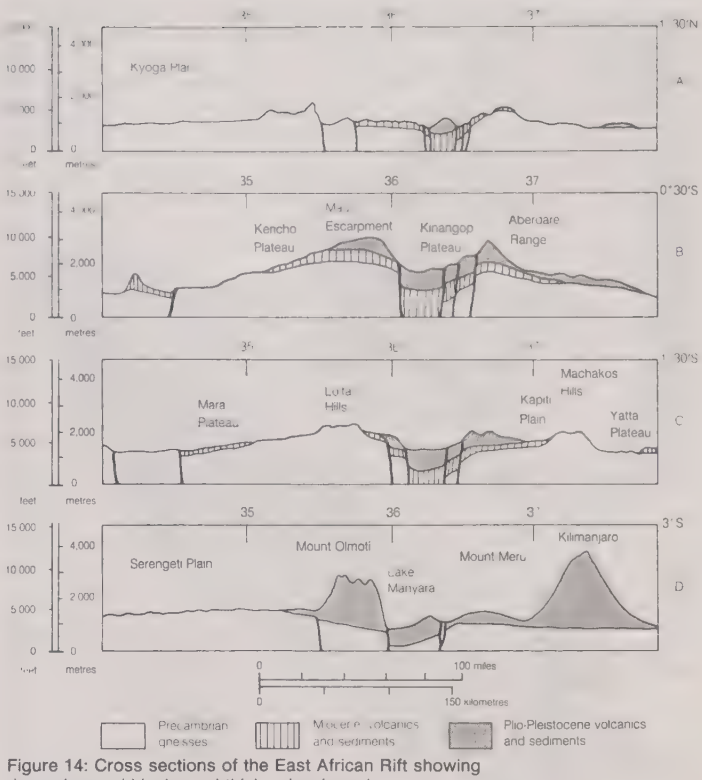

Figure 14: Cross sections of the East African Rift showing down-dropped blocks and thick volcanic rocks.

Adapted from B.H. Baker, P.A. Mohr, and L.A.J. Williams, "Geology of the Eastern Rift System of Africa"; The Geological Society of America, Inc. Special paper 136

PRINCIPAL TYPES

Rift valleys. In the simplest case, a rift valley forms when a block of crust, tens of kilometres wide and hundreds of kilometres long, drops down between two diverging lithospheric plates, much as the keystone in an arch will fall if the walls of the arch move apart. This process is responsible for the relatively symmetrical cross sections of most parts of the East African Rift System, where the valley floor lies 1,000 metres or more below the higher plateaus of Ethiopia and Kenya. In some places, the sides of the rift valley make single, steep walls as high as 1,000 metres. In others, the edges of the valleys consist of steps or tiers with each small inner block dropping with respect to its neighbouring outer block (Figure 14). Thus the deepest part of the rift valley is not always at its centre.

Volcanoes mark the axes of some, but by no means all, rift valleys. Where the lithospheric plates separate and the crust is thinned, the underlying parts of the lithosphere in the mantle also must diverge, allowing hot material from the asthenosphere to rise to shallow depths. Some such material from the asthenosphere has erupted at volcanoes within the eastern rift of the East African Rift System in Ethiopia and Kenya (Figure 14) and within a small section of the western rift in Zaire. Most of the western rift, which extends from Uganda through Lake Tanganyika and Lake Nyasa (Malawi), however, has no volcanoes.

Many rift valleys are asymmetrical with one steep wall and one gentle side. The steep wall is formed by slip on one or two major faults; however, unlike the simple grabens described above, no major fault bounds the other side of the rift valley. Instead, the other side is formed by a flexing of the lithosphere and by a tilting of the surface. Small faults are common, but over all there is a relatively gentle slope into the rift valley. Death Valley, in California, has a very steep eastern margin and a gentler western edge. The floor of Death Valley is moving down along a fault along its eastern margin and is rotating about an axis west of the valley. Thus, the most rapid sinking is along the valley's eastern edge, where the lowest point in the Western Hemisphere, Badwater, lies 86 metres below sea level. Similarly, the Baikal Rift, which contains the deepest lake in the world, Lake Baikal, has a very steep northwestern edge and a gentler southeastern margin.

Within some rift valleys are narrow ridges (10 to 20 kilometres wide) that are bounded by steep sides, separating the ridges from neighbouring parts of the valleys. A ridge of this kind is called a horst, a block of crust bounded by faults such that the flanks of the range have dropped with respect to it. A horst is the opposite of a graben. The third highest mountain in Africa, Margherita Peak of the Ruwenzori Range (located along the border of Uganda and Zaire) marks the highest point on a horst within the western rift of the East African Rift System.

Horst

Horsts can be found in most rift valleys, but unlike the Ruwenzori, they rarely dominate the landscape. The floors of most rift valleys have dropped relative to the surrounding landscape, but the tops of horsts rarely stand higher than the surface outside the valleys. Thus most horsts are merely blocks that have remained at nearly the same height as the unbroken crust outside of the rift valleys. Most horsts exist because rift valleys formed adjacent to them, not because they were elevated.

Some rift valleys, such as the East African Rift Valley in Ethiopia and Kenya, have formed over large domes (Figure 15). Upwelling of hot material within the underlying asthenosphere not only pushes the overlying lithosphere up but heats it as well, causing it to expand. To some extent the upward bulging of the lithosphere causes it to stretch, and this stretching manifests itself as a rift valley. Rift valleys that have formed in this way are commonly associated with extensive volcanism.

Certain rift valleys seem to be created by distant forces acting upon the lithosphere. These valleys cannot be associated with large domes, and in general volcanism is rare or absent. The Baikal Rift, for example, seems to be associated with the same forces that are pushing India into the rest of Eurasia. Moreover, though the elevations of the flanks are high (more than 3,000 metres in some places), the overall elevation decreases rapidly to only a couple of hundred metres at distances of just 50 to 100 kilometres northwest of Lake Baikal. Thus, a broad dome is not present.

Basins and ranges. Some areas, such as the Basin and Range Province of the western United States (Utah, Nevada, and California), contain an extensive network of relatively small tectonic depressions closely akin to rift valleys. The topography consists of basins 10 to 30 kilometres wide and 50 to 200 kilometres long, separated by ranges of similar dimensions. The basins contain young sediment derived from the neighbouring ranges and are quite flat. The sides of the basins can be steep or gentle. Where a major fault separates a basin from a range, the

Basin and Range Province of the western United States

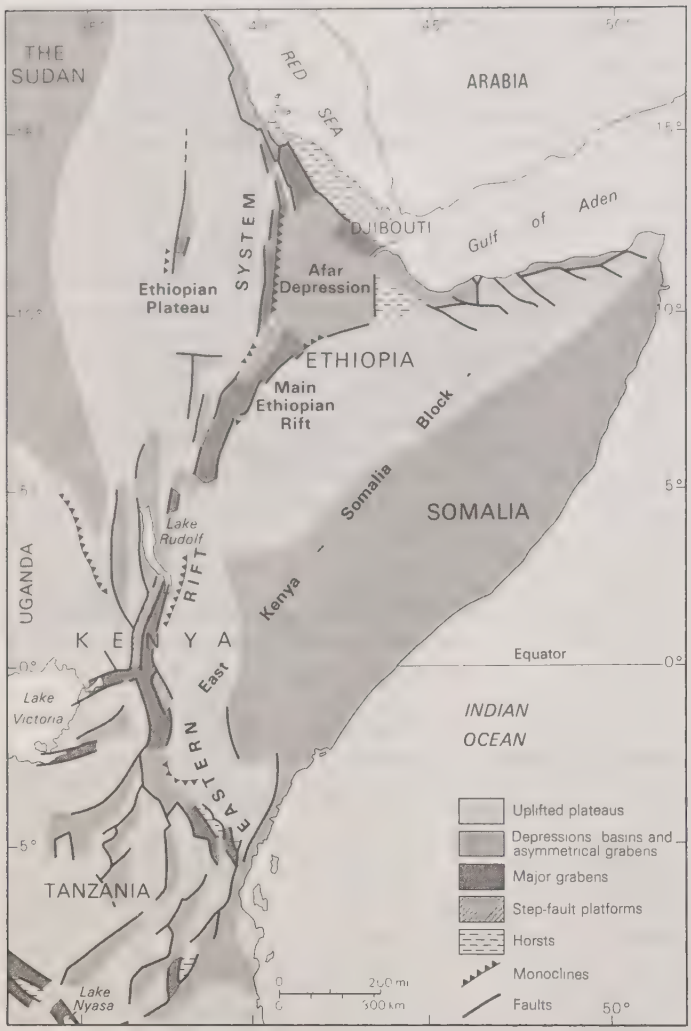

Figure 15: Topography of the eastern rift of the East African Rift System (see text).

Adapted from B.H. Baker, P.A. Mohr, and L.A.J. Williams, "Geology of the Eastern Rift System of Africa", The Geological Society of America, Inc. Special paper 136

edge of the basin is often steep. Where the edge of the basin is produced by the tilting of the basin down and of the range up, the flank is gentle, with average slopes of from a few to 15°. These tilted, gently dipping slopes are particularly apparent wherever lavas, resistant to erosion in dry climates, had flowed onto the surfaces before they were tilted. Such tilted lava-capped surfaces are known as louderbacks. In sum, the tectonic basins of the Basin and Range Province are similar to rift valleys, but their dimensions are smaller, and the ranges are tilted blocks or horsts.

Networks of basins and ranges exist in several other high plateaus. Northerly trending basins lace the Tibetan Plateau; however, unlike those of the western United States, they are more widely spaced, occurring hundreds of kilometres apart. Moreover, a single northerly trending range in Tibet does not in general separate neighbouring basins from one another. The development of a basin and range morphology in Tibet is at a much earlier geologic stage than that of the western United States. The landscape of western Turkey likewise is cut by easterly trending basins and neighbouring ranges that were formed by crustal extension in its north–south dimension. This morphology of basins and ranges extends westward beneath the Aegean Sea. Many of the islands in the Aegean are ranges between basins that stand high enough to poke above sea level. Thus, whereas the dominant feature in a rift valley is the deep wide valley itself, the ranges and valleys are of comparable importance in basin and range topography.

Pull-apart basins. Some tectonic valleys are rectangular or rhomb-shaped basins, bounded by as many as four steep sides. The Dead Sea, the lowest place on Earth, lies 396 metres below sea level at the bottom of just such a basin. Another is the Imperial Valley of southern California, most of which also lies below sea level. These tectonic valleys are closely related to major strike-slip faults—nearly vertical faults along which material on one side moves horizontally with respect to that on the other.

In regions such as the Dead Sea or southern California, nearly parallel strike-slip faults bound two sides of the tectonic valley and end at the valley. Slip on the overlapping segments of the strike-slip faults results in crustal extension in the region between the two faults. Thus two sides of the tectonic valley are bounded by faults with primarily horizontal displacement, and the other two sides are bounded by faults with vertical components of slip. These basins are called pull-apart basins because the crust is literally pulled apart in the section between the two strike-slip faults.

Ramp valleys. As previously noted, these depressions are similar to rift valleys, but they have been formed by the opposite process—crustal shortening. A ramp valley develops when blocks of crust are thrust toward one another and up onto an intervening crustal block. The latter is forced down by the weight of this material, resulting in the formation of the valley. The thrusting of the material onto the intervening crustal block creates high mountains adjacent to the valley.

Formation by crustal shortening

Ramp valleys are characterized by steep sides tens of kilometres apart, and flat floors, which contain debris eroded from the neighbouring mountains. Escarpments on the edges of ramp valleys are not as sharply defined as for simple rift valleys, but the surrounding mountains can be higher than those that bound the latter. To a casual observer, the landscapes of ramp and rift valleys are very similar. In fact, early theories for rift valleys incorrectly attributed their origin to that of ramp valleys.

The most spectacular example of a ramp valley is the Turfan Depression, the second lowest place on Earth (154 metres below sea level), which lies within the Tien Shan of western China and along the northern margin of the Gobi. In general, the rapid filling of ramp valleys in all but the most arid climates makes them ephemeral features; however, small, young ramp valleys can be found in the South Island of New Zealand east of the Southern Alps, and remnants of ramp valleys lie within the Rocky Mountains of the western United States.

Foreland basins. These lie in front of major mountain ranges—*e.g.*, south of the Himalayas, north of the Alps, and east of the Canadian Rocky Mountains. Most basins of this kind are subsurface features, filled with sediment eroded from the adjacent mountain ranges; thus, they are not easily recognized in the flat landscape that is visible. Foreland basins are formed because the overthrusting of the mountains onto a neighbouring lithospheric plate places a heavy load on the plate and flexes it down, much as a diving board is flexed down by the weight of the diver. Foreland basins are deepest and young sediments are thickest next to the mountain range, and the thickness of material decreases gradually and smoothly away from the mountains. The rapid deposition of sediment from the mountains makes a nearly flat surface, such as the Indo-Gangetic Plain of northern Pakistan and India where the Indus and Ganges rivers flow south of the Himalayas. Foreland basins can be important sites of oil and gas reserves. (P.H.M.)

Volcanic and tectonic caves

VOLCANIC CAVES

Caves of various types and sizes occur where volcanic rocks are exposed. These are caves formed by flowing lava and by the effects of volcanic gases rather than by dissolution of the bedrock. (For a discussion of the latter type, solution caves, see below *Caves and karst landscape.*) Because volcanic caves form very close to the land surface, they are easily destroyed by erosional processes. As a result, such caves are usually found only in recent lava flows, those that are less than 20,000,000 years old.

Lava tubes. These are the longest and most complicated of volcanic caves. They are the channels of rivers

Formation in pahoehoe flows

of lava that at some earlier time flowed downslope from a volcanic vent or fissure. Lava tubes develop best in highly fluid lava, notably a basaltic type known as pahoehoe. They rarely form in rough, clinkery aa flows or in the more massive block lavas. In pahoehoe flows volatile components remain in solution in the molten rock where they decrease both the rate at which the lava solidifies and its viscosity. Because of this, pahoehoe lava flows like a sticky liquid, sometimes rushing down steep slopes and forming lava falls.

Process of formation. Near the vent of a volcano, the overflowing lava is directed toward whatever natural channels or gullies are available. As the flow advances downslope, the sides begin to congeal, so that more and more of the flowing lava is confined to a progressively narrowing channel. At this stage, the lava flow behaves like a river moving at relatively high velocity in a narrow canyon. Gradually the surface of the flow becomes crusted over and may also be covered with solid blocks of lava that have been rafted along the flow. As more and more of the surface crusts over, the supply of fluid lava feeding the advancing front of the flow is confined to a roughly cylindrical tube beneath the surface. It is possible in the later stages of crusting to observe the lava river through the few remaining "windows" in the crust.

The development of a channel that feeds the advancing front of the lava flow represents the initial stage in the formation of a lava tube. The second stage is the draining of the original conduit. If the source of lava is cut off at the vent, the fluid lava in the tube continues to flow and the tube drains. The combustion of gases released from the lava maintains a high temperature, and the walls of the conduit may be fused to a black glaze. The draining of the tube may take place in stages, so that benches or ledges are formed along the walls. Lava dripping from the ceiling congeals to form lava stalactites, while lava dripping onto the floor gives rise to lava stalagmites. The floor of a lava tube often has a ropey pattern parallel to the flow direction, showing how the last dregs of the draining lava were frozen into place. Other features of the moving fluid such as trenchlike channels in the floor, lava falls over ledges, ponded lava, and embedded blocks may also be found frozen in place.

General characteristics. In their simplest form, lava tube caves are long tunnels of uniform diameter oriented down the slope of the volcano from which they had their origin (Figure 16). Their roofs and walls consist of solidified lava. In some cases, the floor is covered with sand or other unconsolidated material that has been washed into the cave by water. The roof of a lava tube commonly breaks down, and some caves of this type are littered with blocks of fallen ceiling material. Complete collapse of segments of the roof forms "skylights." When such openings occur at the upper end of a tube, the tube acts as a cold air trap.

D&J McClurg

Figure 16: Rectangular-shaped passage in Bat Cave, Medicine Lake Highlands, near Lava Beds National Monument, California.

Many lava tubes contain ice formations—ponded ice as well as icicles and ice stalagmites where seepage water has frozen in the cold air trapped within the tubes. Some of these ice deposits persist far into the summer.

Complex forms

Lava tubes that have more complicated shapes also occur. Where slopes are gentle, the original lava river may branch into a distributary pattern near the toe. If these are all drained, the remaining tube branches in the downstream direction. New lava flows may override older flows and result in the formation of additional lava tubes on top of existing ones. Sometimes they are connected by younger flows falling through the roof of the older one, thus rejuvenating the older tube. Because most lava flows are thin, lava tubes form near the land surface. Portions of the roof frequently collapse, and the resulting sinkholes provide entrances to the lava tubes. The collapse process also segments the tubes, so that most lava caves have lengths of only a few hundred to a few thousand metres. Often one can line up the individual caves on maps to identify the course of the original tube. Some lava tube caves are found tens of kilometres from the vent where the flow originated.

Other types of lava caves. Small caves are produced in regions of active volcanism by at least three other processes. These are (1) pressure-ridge caves, (2) spatter cone chambers, and (3) blister caves.

The solidified crust of pahoehoe flows often buckles from the movement of lava underneath. The buckled crust appears as ridges several metres to a few tens of metres high, elongated perpendicular to the flow. So-called pressure-ridge caves can be formed beneath the ridges by the mechanical lifting of the roof rock. Such cavities typically measure one to two metres in height, have a roughly triangular cross section, and extend several hundred metres in length. Unlike lava tube caves that are oriented along the flow, pressure-ridge caves are oriented perpendicular to the flow.

Spatter cones

Liquid lava can be forced upward through cracks in the congealed surface layers of the flow. When the ejected blobs of liquid freeze and weld together, they form spatter cones. If the lava subsequently drains from the feeder channel, a dome-shaped chamber is formed beneath such a cone. The depths of these spatter cone pits range from several metres to a few tens of metres.

Trapped steam or other gases can lift layers of lava while it is still in a plastic state to form small blister caves. These cavities consist of dome-shaped chambers somewhat resembling those of spatter cones. They are generally small, ranging from one to a few metres in diameter, but they often occur in great numbers in many lava flows rich in volatile components.

In the United States lava caves are found chiefly in the Pacific Northwest—northern California, Washington, Oregon, and Idaho—and in Hawaii. One of the longest (measuring 3.4 kilometres) is Ape Cave on the flank of Mount St. Helens in Washington. The cave is located on the side of the volcano opposite that involved in the catastrophic eruption of 1980 and so survived the outburst. Ape Cave is only one fragment of a series of interrelated lava tubes that mark a continuous flow path down the volcano. A large number of lava tubes also occur beneath a nearly flat plain in the Bend region of central Oregon. Many of these are related to fissure eruptions rather than to a single volcanic cone. Lava tubes are commonly found in other young volcanic regions of the world, notably in the Canary Islands, on Iceland, along the East African Rift Valley, and in parts of Australia.

TECTONIC CAVES

Tectonic caves are formed by a mass movement of the bedrock. The rocks separate along joints or fractures, and are pulled apart mechanically. The resulting cave is usually a high, narrow fissure that has nearly planar walls with matching patterns on opposite sides of the passage. The ceiling is often a flat bed of rock that did not move or that moved along some different fracture. The floor of a tectonic cave may consist of massive bedrock or of a rubble of fallen blocks, or it may be covered with soil and other material washed in from the surface.

Because tectonic caves are formed by mechanical processes, the most important characteristic of the bedrock is that it be mechanically strong. Massive, brittle rocks such as sandstones and granites are the best host rocks for tectonic caves.

Importance of gravity sliding in the formation of tectonic caves

Although tectonic caves can be formed by any geologic force that causes rocks to move apart, the key mechanism is gravity sliding. The optimum setting for the development of tectonic caves occurs where massive rocks dip gently to the sides of ridges or mountains. The presence of shale layers between beds of massive sandstone can act as a lubricating layer and facilitate mechanical slippage. Gravity causes the massive rocks to slip and separate along vertical fractures, which then become tectonic caves. The amount of slippage must be small for the cave to maintain its roof. Too much slippage and consequent roof collapse will form an open canyon. Still more slippage can result in a landslide.

Tectonic caves occur in many geologic settings and in great numbers, since they are produced by minor slippages in outcrops of massive sandstones, granites, basalts, and even limestone. Tectonic caves are among the most common caves, but they are rarely noticed or catalogued. They contain few, if any, features that attract attention and usually are quite small. Most such caves measure from several metres to a few hundred metres in length. Many of them consist of a single passage that extends into hillsides along major fractures. Some of the larger tectonic caves have a grid or network pattern that matches the pattern of the fractures or joints. (W.B.Wh.)

STRUCTURAL LANDFORMS

Treated in this section are the topographic features formed by the differential wearing away of rocks and the deposition of the resulting rock debris under the influence of exogenetic geomorphic forces. Such forces operate at the interface of the planetary atmosphere, lithosphere, cryosphere, and hydrosphere. The processes generating these forces are the major agents of erosion, transport, and deposition of debris. These include fluvial, eolian, glacial, groundwater, and coastal-marine processes, as well as those associated with mass movement. Structural landforms result from forces generated by these processes interacting with resistances, imposed by rocks and sediments. For change to occur, the forces must exceed the thresholds of resistance imposed by the earth materials on which they act. The landform itself, however, may alter the forces by developing specific shapes. Sand dunes, beaches, river valleys, and glacial drumlins are all examples of landforms that modify the forces imposed upon them. Such self-regulation of landform development is a quality of landscapes that achieve equilibrium.

Although structure and lithology establish the resistance factors for structural landforms, climate defines the nature of the exogenetic geomorphological processes. In cold regions ice-related processes dominate in the development of landscapes, while in warm-wet regions fluvial processes exert primary control. Thus, a climatically controlled style of landscape development is imposed on the structurally defined surface. Moreover, process and structure interact through geologic time on an evolving landscape. As pointed out by the eminent William Morris Davis, landscape is a function of the trilogy of structure, process, and time (see above).

Stream valleys and canyons

Wherever sufficient rainfall occurs, opportunity exists for the land surface to evolve to the familiar patterns of hills and valleys. Of course, there are hyperarid environments where fluvial activity is minimal. There also are geomorphological settings where the permeability of rocks or sediments induce so much infiltration that water is unable to concentrate on the land surface. Moreover, some landscapes may be so young that insufficient time has elapsed for modification by fluvial action. The role of fluvial action on landscape, including long-term evolutionary processes, is considered here in detail. For additional information on fluvial and hillslope processes relating to valley formation, see GEOMORPHIC PROCESSES and RIVERS.

Effects of fluvial action

Probably the world's deepest subaerial valley is that of the Kāli Gandak River in Nepal. Lying between two 8,000-metre Himalayan peaks, Dhaulāgiri and Annapūrna, the valley has a total relief of six kilometres. Because the Himalayas are one of the Earth's most active areas of tectonic uplift, this valley well illustrates the principle that the most rapid downcutting occurs in areas of the most rapid uplift. The reason for this seeming paradox lies in the energetics of the processes of degradation that characterize valley formation. As will be discussed below, the steeper the gradient or slope of a stream, the greater its expenditure of power on the streambed. Thus, as uplift creates higher relief and steeper slopes, rivers achieve greater power for erosion. As a consequence, the most rapid processes of relief reduction can occur in areas of most rapid relief production.

A canyon is a deep and very narrow type of river valley. Perhaps the most famous example is the Grand Canyon of the Colorado River in northern Arizona (Figure 17). The Grand Canyon is about 1.6 kilometres deep and 180 metres to 30 kilometres wide and occurs along a 443-kilometre long reach where the Colorado River incised into a broad upwarp of sedimentary rocks.

GEOMORPHIC CHARACTERISTICS

Primacy of fluvial action

The relief of valleys and canyons is produced by the incising action of rivers. Hillslope processes are indeed critical in the development of valley sides (see below), but it is rivers that lower the level of erosion through degradation. Rivers ultimately adjust to a baselevel, defined as the lowest point at which potential energy can be transformed to the kinetic energy of river flow. In most cases, the ultimate baselevel for rivers is sea level. Some rivers drain to enclosed basins below sea level, as, for example, the Jordan River, which flows to the Dead Sea in Israel and Jordan. Moreover, rivers may adjust to local baselevels, including zones of resistance to incision, lakes, and dams (both natural and artificial).

Valley longitudinal profiles. The longitudinal profile of a valley is the gradient throughout its length. Valleys formed by river action typically have a concave upward profile, steep in the headwaters and gentle in the lower reaches. The lower end of such a profile is adjusted to an effective lower limit of erosion defined by the baselevel (Figure 18).

In an ideal case of river adjustment to uniformly resistant materials, the longitudinal profile of a stream assumes a characteristic form that minimizes variations in trans-

Figure 17: Grand Canyon of the Colorado River in northern Arizona.

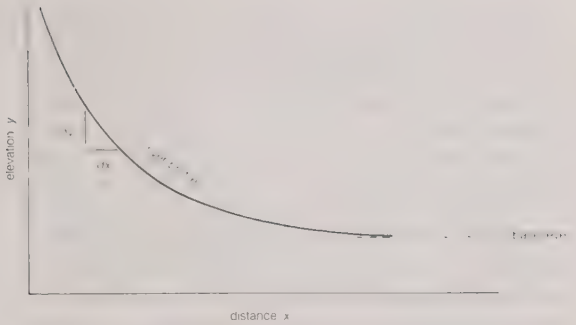

Figure 18: Simplified concave upward longitudinal profile of a river that illustrates the concept of base level and the defining terms used in calculating stream power.

porting power. Power in a river derives from the rate of transfer of potential energy, dE/dt, which depends on the rate of fall in elevation of water, dy/dt, according to

$$\frac{dE}{dt} = m\,g\,\frac{dy}{dt}, \tag{1}$$

Where E is energy, t is time, m is mass, g is the acceleration of gravity, and y is elevation. The rate of fall in elevation, in turn, can be expressed as follows:

$$\frac{dy}{dt} = \frac{dy}{dx}\,\frac{dx}{dt} = S\,V, \tag{2}$$

where S is the slope (fall in elevation, dy, with downstream horizontal distance, dx), and V is the flow velocity (change in horizontal distance, dx, with time, dt).

Combining equations (1) and (2) and using the fluid density ρ (mass per unit volume of water), one obtains

$$\frac{dE}{dt} = \rho\,g\,(W \cdot D \cdot L)\,S\,V, \tag{3}$$

where W is channel width, D is channel depth, L is a unit length of stream, and the other parameters are as defined above. Because flow discharge Q is defined as

$$Q = W \cdot D \cdot V, \tag{4}$$

the power per unit length of flow, Ω, can be expressed as

$$\Omega = dE/dt/L = \rho\,g\,Q\,S. \tag{5}$$

It should be noted that in order to minimize variation in power, a river increasing its discharge in a downstream direction must decrease its slope. Thus, slope must be constantly decreasing downstream, explaining the concave upward character of the longitudinal profile.

The idealized concave upward longitudinal profile defined purely by energy considerations, noted above, only occurs where channel bed resistances and adequate adjustment time permit. Resistant zones of bedrock require greater power for a stream to incise at a given discharge Q than do less resistant zones. Therefore, by equation (5) the stream gradient S must be locally steeper at resistant zones. Similarly, a rapid base-level change, such as a fall of sea level, may not allow adequate time for the entire longitudinal profile to adjust. One indication of such effects on a longitudinal profile is a nick point, or abrupt change in slope of the profile.

Valley cross profiles. The cross profiles of valleys involve a combination of fluvial and hillslope processes. Although slopes and rivers are often studied separately by process geomorphologists, hills and valleys are the features that dominate landscapes. In upland areas cross profiles of valleys are often narrow and deep. Canyon morphologies are most common. Further downstream, valley floors are wider and often dominated by floodplains and terraces.

Classification scheme

Types of valleys. One of the few classifications of valleys is that used by the German climatic geomorphologists Herbert Louis and Julius Büdel. In areas of rapid uplift and intense fluvial action such as tropical mountains, *Kerbtal* (German for "notched valley") forms occur. These are characterized by steep, knife-edge ridges and valley slopes meeting in a V-shape. Where slopes are steep but a broad valley floor occurs, *Sohlenkerbtal* (meaning precisely a valley with such characteristics) is the prevailing form. Valleys of this kind develop under the influence of groundwater flow in Hawaii (see below *Processes*). Gutter-shaped valleys with convex sides and broad floors are called *Kehltal;* and broad, flat valleys of planation surfaces are termed *Fachmuldental.*

It is important to remember that the form of valleys reflects not only modern processes but also ancient ones. The entire valley or some landforms within it may be relict, with features inherited from past geologic periods during which occurred tectonic and climatic processes of intensities quite different from those prevailing today.

Hillslopes. Hillslopes constitute the flanks of valleys and the margins of eroding uplands. They are the major zones where rock and soil are loosened by weathering processes and then transported down gradient, often to a river channel.

Principal hillslope types

Two major varieties of hillslopes occur in nature (Figure 19). On weathering-limited slopes, transport processes are so efficient that debris is removed more quickly than it can be generated by further weathering. Such hillslopes develop a faceted or angular morphology in which an upper free face, or cliff, contributes debris to a lower slope of accumulation. Slopes of this sort are especially common on bare rock where the profile of the slope is determined by the resistance of the rock, not by the erosional processes acting on it. One consequence of this is that many rock slopes retreat parallel to themselves in order to preserve the characteristic slope angle for a rock type of given strength. If the features of the rock change with depth into the slope, however, the characteristic angle of the slope will change. Rock slopes develop where weathering and soil erosion are slow (as in arid regions) and where rock resistance is high.

The second major variety of slope is transport limited. Transport-limited slopes occur where weathering processes are efficient at producing debris but where transport processes are inefficient at removing it from the slope. Such slopes lack free faces and faceted appearances, and they are generally covered with a soil mantle. The profile of this type of slope generally has a sigmoid appearance, with convex, straight, and concave segments. The shape of the slope is an expression of the process acting upon it.

Convex slope segments commonly occur in the upper parts of soil-mantled slopes, as near the drainage divide. The noted American geomorphologist G.K. Gilbert elucidated the principles applying to convex slopes in his study of piles of mining-waste debris in California. The processes of soil creep and raindrop splash erode soil on the upper parts of slopes. Since soil eroded from the upper slope must pass each point below it, the volume of soil moved increases with distance from the divide. Since the transport rate for creep and rain splash is proportional to the slope angle, the slope angle must also increase from the divide, resulting in the slope convexity.

Straight slope segments are dominated by mass movement processes. Talus slopes are a type in which debris piles up to a characteristic angle of repose. When new debris is added to the slope, thereby locally increasing the angle, the slope adjusts by movement of the debris to reestablish the angle. Again, the result is a dynamic equilibrium in which the landform adjusts to processes acting upon it.

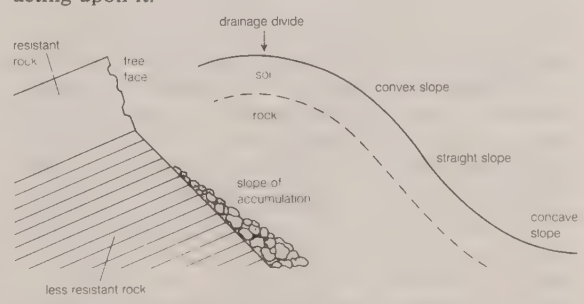

Figure 19: Comparison of idealized profiles for weathering-limited, faceted hillslopes (left) and transport-limited, sigmoid hillslopes (right).

Concave slopes are especially common where overland-flow runoff transports sediment derived from upper slopes. Because the collection area for wash increases downslope and discharge Q is proportional to collection area, stream power—equation (5)—can be maintained at lower slope angles. In addition, the size of particles being transported decreases downslope because of weathering and abrasion. Because the finer particles are easier to transport, slope angles can be reduced in the downslope direction. The result is a concave shape to the slope profile.

ORIGIN AND EVOLUTION

River valleys figure prominently in the evolutionary sequence of landscape development conceived by W.M. Davis (see above *Davis' erosion cycle theory and related concepts*). Unfortunately Davis' marvelous deductive scheme of progressive landscape change with time was somewhat abused by those who employed it merely for description and classification. By the mid-20th century, the focus of geomorphological research shifted from evolutionary sequences to studies of processes. Today, new procedures for radiometric dating have rekindled interest in long-term landscape evolution.

Valley development with time can be conceived of as a functional relationship, as follows:

$$v = f(c, r, l, p, t), \tag{6}$$

where v is the valley morphology, c is the climate, r is relief factors including slope, l is lithology and rock structure, p is the type of process operating (surface runoff or spring sapping), and t is time.

Significance of drainage density

Valley morphology can be described in numerous ways. A useful measure is drainage density Dd, which relates the length of valleys (or streams) L to the area A in which they occur:

$$Dd = \frac{\Sigma L}{A}. \tag{7}$$

In many applications, A is defined as the drainage area in which a network of valleys is developed. There is a close relationship of drainage density to hillslope angles and local relief. For a given relief, higher drainage density results in short, steep valley-side slopes. For the same relief, a lower drainage density results in long, gentle slopes.

Processes. *Runoff processes.* When rain falls on a land surface, part of it may infiltrate, depending on the rate of rainfall and the permeability of the substrate. The amount of rainfall that exceeds the infiltration capacity collects in pools and eventually flows over the land surface. This process of overland flow is quite inefficient because a large surface area greatly resists water movement. Depending on the substrate resistance and power of the flow, the tendency is to incise to form a channel. This transition from overland flow to channel flow is the first step toward a response to rainfall input. Eventually the dissection by channels leads to the differentiation of hills from valleys.

Not all the rainfall is transformed to overland flow and infiltration to groundwater. A portion is lost to evaporation and to transpiration by plants. What eventually flows off the landscape from surface and subsurface sources is the runoff R given by

$$R = P - ET \pm S, \tag{8}$$

where P is the precipitation and ET is the combination of evaporation and transpiration; S is a storage term for water held in plants, soils, and subsurface rocks. The overland flow component of runoff appears very quickly after storms, while the subsurface flow components appear much more slowly. In channels, all forms of runoff generate increased stream power because of increased discharge. This allows streams to incise, thereby deepening valleys, which may widen through hillslope processes.

Sapping. Sapping is a process of hillslope or scarp recession by the undermining of an overlying resistant material in the form of weathering or water flow occurring in an underlying less-resistant material. A variation of this process, spring sapping, occurs where groundwater outflow undermines slopes and, where appropriately concentrated, contributes to the development of valleys. The action of groundwater in sapping may be concentrated at valley heads, leading to headward growth. Both enhanced weathering and direct erosion by the concentrated fluid flow lead to slope undermining and collapse at sites of groundwater outflow.

Spring sapping

A conceptual model of valley development by sapping can be envisioned with the initial condition of a water table having a regional slope toward a hydraulic sink provided by a depressed region. Water emerging along a spring line would then foster chemical weathering and thereby increase the porosity of the seepage zone, reducing the local rock tensile strength and rendering the weathering zone more susceptible to erosional undercutting of adjacent slopes. Local zones of heterogeneity in the rock will result in some zones achieving the critical conditions necessary for such undermining before other zones achieve them. Joints, faults, and folds serve this function. These critical zones then experience enhanced undermining. Once initiated, this process becomes self-enhancing because the lines of groundwater flow converge on the spring head. The increased flow accelerates chemical weathering, which leads to further piping at the same site.

The farther a spring head retreats, the greater the flow convergence that it generates, thereby increasing the rate of headward erosion. Headward sapping proceeds faster than valley widening because the valley head is the site of greatest flow convergence. Headward growth, however, may intersect other zones that are highly susceptible to sapping. A particularly favourable zone will result in a tributary that also experiences headward growth and that may generate tributaries of its own. Thus, sapping that occurs in a zone of jointing or faulting will develop a pattern aligned with those structures. It will, however, be organized by the hydraulic controls on the groundwater flow.

This process of sapping, headward retreat, and branching eventually forms a network of valleys. The developing network works to counteract the self-enhancing effect of flow concentration mentioned above. As spring heads migrate to the neighbourhood of one another, their demands for the available groundwater compete with each other. Eventually an equilibrium is achieved at some optimum drainage density.

Excellent examples of valleys formed by sapping are found in the massive sandstone terrains of the Colorado Plateau. Groundwater seepage from the sandstone contributes to local disintegration of the bedrock at the bases of cliffs, thereby undermining slopes and leading to backwearing. Because of structural concentration of water flow along joints and faults, valleys grow headward along zones of structural weakness. Canyons formed by sapping have prominent structural control vertical to overhanging walls, flat floors, elongate shape, low drainage density (leaving undissected uplands), relatively short tributaries to main trunk valleys, irregular variation in valley width as a function of valley length, and theatre-like valley heads. Many of the sapping valleys of the Colorado Plateau are probably relict features, since lowered water tables and/or dessicating climatic conditions have in all likelihood resulted in reduced groundwater flow to the valley floors today. During wetter climatic episodes of the Quaternary (from about 2,000,000 years ago to the present), which probably coincided with periods of mountain glaciation, spring sapping activity would have been more pronounced. Under modern climatic conditions, the results of past spring-sapping processes are obscured by the modifying action of non-sapping morphogenetic processes.

Canyons formed by sapping processes

Valley evolution in Hawaii. The Hawaiian Islands comprise a chain of volcanic islands, with ages increasing progressively to the northwest from the island of Hawaii with its active volcanoes, Kilauea and Mauna Loa. In general, the dissection of the Hawaiian volcanoes also increases with age to the northwest, but the details of dissection are considerably influenced by climate, factors related to parent material, and changes in process. Nevertheless, a remarkable opportunity to study valley development with time is afforded by the phenomenon of the northwesterly movement of the Pacific Plate carrying a succession of volcanoes away from a stationary mantle plume (rising jet

of partially molten rock material) located at the southern tip of Hawaii.

Rainfall is heaviest on the northeastern slopes of the volcanoes because of the prevailing trade winds. Although this results in generally higher drainage densities on the windward rather than leeward slopes of islands such as Hawaii, there are important exceptions. Mauna Loa, for example, lacks dissection on its northeastern flanks in spite of having the same amount of rainfall as highly dissected parts of Mauna Kea. Such is the case because the basaltic lava flows of the volcanoes are so permeable that drainage will not develop until a less permeable ash mantle is emplaced or until weathering reduces infiltration. Examples of both phenomena occur in Hawaii. Kilauea Volcano, the youngest of the Hawaiian shields, displays essentially no dissection except where ash from the 1790 Keanakakoi eruption was emplaced. The older Mauna Loa and Mauna Kea shields display V-shaped ravines only where their flanks were mantled by Pahala ash. Dissection is more pronounced on Mauna Kea, which is older than Mauna Loa. Kohala Volcano is the oldest shield on the island of Hawaii, having formed about 700,000 years ago. Deep weathering of its basalt has reduced infiltration sufficiently to promote high-density drainage on its northeastern slopes.

Valley initiation on the Hawaiian volcanoes thus depends on rainfall and infiltration capacity. When runoff valleys are initiated, their streams incise to form V-shaped ravines. The ravine systems eventually become deep enough that they expose deeper layers where groundwater activity and spring sapping become more important (Figure 20). The deepest incision produces U-shaped, theatre-headed valleys. Because the layered basalt flows are most permeable parallel to dip, there is efficient groundwater movement toward the sea. The regional water table on the islands is near sea level, with a slight bulge in the central parts of the islands that have a gentle seaward slope in all directions.

Formation of deep U-shaped valleys

The U-shaped sapping valleys of the older Hawaiian volcanoes display enhanced weathering at the water table. This undermines the side slopes of the valleys, so that their steep-sided walls meet their floors at a sharp angle (Figure 21). The valleys widened laterally as they were developed by headward growth of springs at the valley heads. Perennial flow was maintained by large springs.

Channels and valleys on Mars. At least one other planetary body in the solar system besides the Earth is dissected by valleys of fluvial origin—namely, Mars. The heavily cratered terrains of Mars are extensively dissected by interconnected, digitate networks of valleys. Many of the valleys are steep-walled and have theatre-like headward terminations, especially near the equatorial regions of the planet. Additional properties include common structural control of the networks, low drainage densities, and low junction angles with tributaries. This combination of features seems best explained by a sapping mechanism for much of the valley formation.

Network of ancient stream valleys

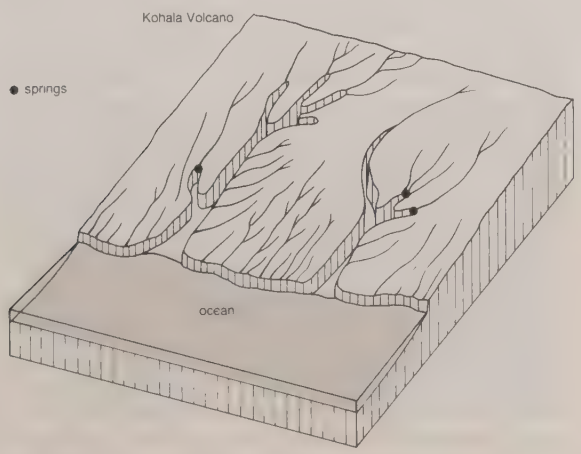

Figure 20: Association of V-shaped ravines and deep valleys enhanced by spring sapping as typical of valley development on Hawaiian volcanoes.

Figure 21: Large U-shaped valleys developed on Kohala Volcano, Hawaii.

The valleys of Mars are for the most part extremely ancient. Very large numbers of craters are superimposed on the valleys, indicating that they formed about the time of the phase of heavy bombardment early in the history of the solar system.

Another variety of valley on Mars occurs at fairly high latitudes where temperatures are colder. These valleys have rounded, subdued wall topography, and their floors are covered with debris that appears to have been produced from the walls and flowed across the floors. Masses of similar debris surround isolated massifs. It is probable that subsurface ice facilitated the production and flowage of the debris in a manner similar to what is observed in the Earth's periglacial regions.

Influence of structure. The role of structure in drainage development may be passive, in which case the composition of rocks and various rock discontinuities (joints, faults, and bedding) dictate the details of erosion. In this way, structure provides the boundary conditions for landscape degradation. During tectonism, such as faulting and folding, structural controls change with time, and the erosional system must adjust to changing resistances. Different structural controls also are encountered as incision of streams exposes lower units in the Earth's crust.

Over the years, Russian and eastern European investigators have emphasized structural control in geomorphic analysis. I.P. Gerasimov defined structural units of the landscape called morphostructures as terrain types generated by a combination of tectonic activity and climate. Various morphostructures are produced by alternating periods of uplift (with resulting dissection) and stabilization (yielding planation surfaces). The history of a morphostructure and regional tectonism can be studied by analyses of river terraces, planation surfaces, and correlative sedimentary deposits.

Morphostructures

Drainage patterns. The pattern of fluvial dissection of a landscape is of considerable importance in understanding the structural influence on drainage evolution. Dendritic patterns (Figure 22), so called because of their similarity to branching organic forms, are most common where rocks or sediments are flat-lying and preferential zones of structural weakness are minimal. The conveyance properties of a dendritic network are analogous to blood circulation systems and tree branching. Rectangular and angular patterns occur where faults, joints, and other linear structures introduce a grain to drainage. Where a broad tilt or regional slope occurs on a surface of otherwise uniform resistance, a parallel pattern occurs. Special drainage patterns characterize belts of parallel folds (trellis pattern), domes or volcanoes (radial pattern), and other landscape types.

In a series of tilted sediments the differential erosion of softer units, such as clay and shale, results in valleys developed perpendicular to the dip or tilt of the units. These strike valleys are paralleled by ridges of the tilted sediments called cuestas. Another term for a strike stream, which

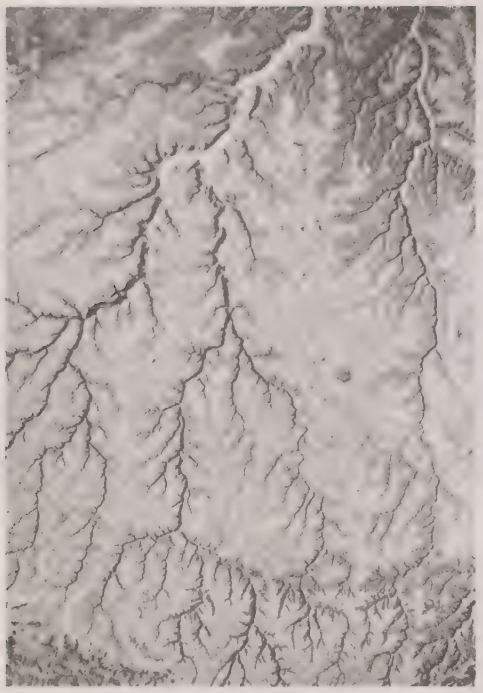

Figure 22: Dendritic drainage pattern developed on flat-lying limestone in central Yemen.
By courtesy of National Aeronautics and Space Administration

parallels the structural grain, is a longitudinal stream. In contrast, transverse streams cut across structural trends. Streams flowing down the tilted sediments of the cuesta are called dip streams because they parallel the structural dip of the strata. Streams draining the cuesta scarp into longitudinal valleys flowing opposite to the structural dip are called antidip streams.

Cross-axial drainage. One of the most interesting anomalies that occurs in drainage evolution is the development of stream courses across the axes of structural zones (*e.g.,* upwarps and fold belts). Some examples of cross-axial, or discordant, drainage include rivers that appear to take the most difficult routes possible through folded regions such as the Appalachian Mountains of the United States and the Zagros Mountains of Iran. The classical studies of cross-axial drainage were made during the exploration of the Colorado River system in the 19th century by the American geologist John Wesley Powell. The Colorado River and its tributaries cross great structural upwarps. Rather than flowing around domes or plunging folds, the rivers carved canyons into what appears to be paths of greatest resistance. One theory posed by Powell for such relationships is that of antecedence. According to this view, the rivers were already in their present positions when the various anticlinal folds and upwarps began to grow. A relevant analogy is a saw into which a log is being pushed. The saw represents the river and its continuing degradation, and the log represents the growing upwarp.

Possible explanations for cross-axial drainage

Another possible origin of cross-axial drainage is superimposition. According to this theory, a cover of sedimentary material must bury older structures. The river develops on this overlying sedimentary cover and subsequently imposes its pattern across the underlying structures as they are exposed by continuing degradation.

A third explanation for cross-axial drainage is that of inheritance. In this hypothesis, an erosion surface is developed across the structure zone by long-continued planation. When the streams incise, abandoning the former planation surface, they become imposed across the structures. Alternatively, the stream may actually exploit zones of weakness or minimal resistance as it downcuts from former levels. Stream capture (also called stream piracy) occurs as more aggressively eroding portions of the drainage cut through divides. In many cases, a complex combination of the above processes probably occurs to yield the final result.

Stream capture

Stream capture is especially common where longitudinal streams flowing on the weaker rocks of a fold belt erode into the valleys of transverse streams that must cross the resistant strata. Sections of valley abandoned after such captures are known as wind gaps. These contrast with the water gaps that still contain transverse streams. The famous water gaps of the Appalachians are excellent examples of such patterns.

Influence of climate. The importance of climate in landscape evolution, particularly valley development, has been emphasized by many European geomorphologists. Jean Tricart and André Cailleux of France and Julius Büdel of Germany developed climatic geomorphology as a synthesis of relief-forming processes. Climatic geomorphologists define systematic morphoclimatic zones on the globe in which relief-forming mechanisms differ as a function of climate. Some of the important morphoclimatic zones are briefly outlined in the following sections.

Periglacial zone. The term periglacial relates to cold-climate processes and landforms (see below *Periglacial landforms*). The most important periglacial influence on valleys is frost action, which produces abundant debris by freeze-thaw action on rock and soil. During the coldest periods of the Quaternary (the last 1,600,000 years), the periglacial zone was enlarged to approximately twice its present extent. Hillslopes became mantled with frost-shattered rubble that moved downslope during cycles of freezing and thawing. The relicts of this periglacial activity characterize much of the modern humid-temperate zone—*e.g.,* in portions of Pennsylvania and Wisconsin in the United States and England and Poland.

Arid zone. In arid regions moisture conditions are inadequate to support abundant vegetative cover of the land surface. As a result, the land is subjected to intense fluvial, eolian, and mass-wasting processes. The importance of fluvial action may seem ironic for an arid region. Although most arid regions receive little rainfall, the amount that falls is especially effective. Rare but intense arid-region rainstorms act upon a landscape that is unprotected by vegetation. Of course, some hyperarid regions receive such infrequent rainfall that fluvial processes are indeed ineffective. Nevertheless, even the most arid places on Earth show evidence of fluvial activity, either because of wetter conditions in the past or because of very rare rainstorms.

Tropical zone. Tropical regions are dominated by dense vegetative cover and deep weathering profiles. In continuously humid tropical zones, fluvial activity is facilitated by intense rainfall but inhibited by the protective effect of rain forests. The lateritic soils of these regions, however, do not promote deep root penetration, and the vegetative cover may be undermined by fluvial erosion or mass movement. Fluvial activity may be quite intense in the tropics, especially in tectonically active areas. In more stable cratons, however, the landscape is dominated by low-relief planation surfaces. Rivers flowing on the deeply weathered regolith of these surfaces have low stream power and transport mainly fine-grained weathering products. Thus, immense contrasts in fluvial activity exist in the tropics.

At higher tropical latitudes, the continuously humid zone of the Equator changes to a zone of seasonal rainfall. Such regions have savanna vegetation because of prolonged dry seasons. Erosion rates may be extremely high in savanna environments.

Role of climatic change. Because the Earth's climate has changed profoundly during the Quaternary and Tertiary (roughly the past 65,000,000 years), many landscapes are palimpsests—*i.e.,* they are composed of relict elements produced under the influence of past climates and modern elements produced in the present climatic regime. The study of such landscape changes is sometimes called climato-genetic geomorphology. Some researchers in the field, notably Büdel, have maintained that little of the extant relief in humid temperate regions of the Earth results from modern relief-forming processes. Rather, they believe, much of the familiar humid temperate landscape is inherited from past climatic conditions, including periglacial, arid, and tropical.

The views of the climato-genetic geomorphologists

Büdel focused attention on differences in the nature of valley formation as a function of climate through the

history of a landscape. He argued that very rapid valley formation accompanied periods of periglacial activity in central Europe. Modern rivers in the region seem less effective at valley incision. Most of them flow on fills within great bedrock valleys, indicating that aggradation rather than downcutting is occurring today. Prior to the Quaternary phase of valley cutting, central Europe in the Tertiary seems to have experienced a prolonged period of planation, resulting in low-relief plains. Büdel proposed that the remnants of these Tertiary plains, now preserved as broad planar uplands, are inherited from a time of tropical planation. Remnants of a former tropical regolith on the uplands provide some evidence for this hypothesis.

Paleovalleys. The southwestern desert of Egypt is one of the most arid places on Earth. The region lacks surficial traces of active fluvial processes and is dominated by eolian activity. In this region, a research team headed by John F. McCauley of the U.S. Geological Survey discovered in 1982 that the local drift sand had buried an array of valleys and other relict fluvial features. The discovery was made possible by the imaging radar system of the U.S. Space Shuttle, which penetrated several metres of the extremely dry sand to reveal the previously unknown valleys. The relict valleys were probably part of Late-Tertiary river systems that drained the eastern Sahara during relatively wet climatic conditions prior to the onset of hyperaridity in the Quaternary.

Relict river valleys of the eastern Sahara

A very important American paleovalley involves the complex history of the Ohio River. Prior to the glacial phases of the Quaternary, the preglacial predecessor of the Ohio drained northwestward from the Appalachians across the Midwest, but far north of its present course. Numerous water wells in Ohio, Indiana, and Illinois are located along this paleovalley, which is called the Teays River System. The advances of Quaternary ice over the course of the Teays River eventually caused the drainage to shift from the Teays route to one roughly paralleling the glacial boundary. The modern Ohio River is the product of this heritage.

Misfit streams. Another manifestation of the impact of climatic change is the misfit stream. Such streams are those for which some practical measure of size, most often the meander wavelength, indicates that the modern river is either too large or too small for the valley in which it flows. The former condition, known as an overfit stream, is relatively rare. An example, described below, occurs where cataclysmic glacial floods invaded valley systems formed by overland flow processes in a non-glacial climatic regime. The more common case is the underfit stream, in which valley morphology indicates a larger ancient stream (Figure 23).

Overfit and underfit streams

The English-born geomorphologist George H. Dury developed a theory for the widespread phenomenon of stream underfitness. He believed that, when the larger valley forms developed, climatic change was required to reduce the channel-forming discharges from past highs to the modern shrunken channel dimensions. Dury argued that the last phase of stream shrinkage occurred at the end of the last glaciation when the global climate changed from cool and moist to warm and dry. He quantified his theory, utilizing the relationship between the wavelength of modern meandering rivers (λ) and their bank-full discharge (q_b),

$$\lambda = 54.3\ q_b^{0.5}, \tag{9}$$

where the units of λ and q_b are metres and cubic metres per second, respectively.

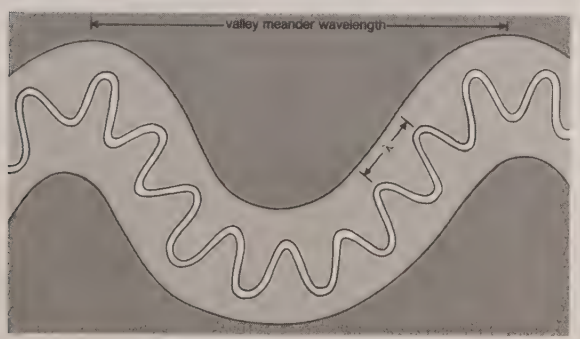

Figure 23: Idealized map view of a stream that is underfit in relation to its valley. The contrast between the meander wavelength λ of the modern river and that of the valley is apparent.

Using equation (9), Dury found that since valley meanders were five to 10 times larger than modern river meanders, the ancient bank-full discharges must have been 25 to 100 times larger than the modern values. Such large modifications implied a phenomenal climatic change that was not accepted by the general scientific community. Numerous other factors besides climatic change play a role in the development of underfitness. These include changes in the type and amount of sediment transported by streams, the role of different rock types in shaping valley dimensions, and the role of large, rare floods (as opposed to bank-full discharge) in defining channel dimensions. The problem of underfitness remains a challenge awaiting complete geomorphological explanation.

Probably the most remarkable example of a misfitness is the channeling of the basaltic plain of eastern Washington in the northwestern United States by cataclysmic glacial floods. The great floods emanated from glacial Lake Missoula, which was impounded between about 17,000 and 12,000 years ago by a lobe of the Cordilleran ice sheet that extended into northern Idaho. Failure of this ice dam released a lake volume of about 2,500 cubic kilometres at discharges of up to 2×10^7 cubic metres per second. These immense flows completely overwhelmed the preglacial stream valleys of the Columbia Plain in eastern Washington. As the floods eroded loess and bedrock from former valley divides, a great plexus of scoured channel ways known collectively as the Channeled Scabland was formed. Because preglacial valleys were filled to overspilling, this process is really an example of stream overfitness. Numerous diagnostic landforms, including great cataracts, characterize the Channeled Scabland.

The Channeled Scabland

The above relationships were first described in the 1920s by the American geologist J Harlen Bretz, who contended that the Channeled Scabland could only be explained by the action of cataclysmic flooding. He encountered vehement opposition to this hypothesis but was eventually able to convince most of his critics of its validity by carefully documenting the overwhelming evidence for flood-produced landforms. Of considerable importance was the discovery of giant current ripples composed predominantly of gravel. More than five metres high and spaced 100 metres apart, these current ripples occurred on large bars of gravel and boulders.

The channels of Mars. The landforms produced by large-scale fluid flow in the Channeled Scabland are remarkably similar to those in the channeled terrains of Mars. In contrast to the Martian valley networks (see above), the channels of the planet display evidence of large-scale fluid flows on their floors. Most Martian channels show that the erosive fluid emanated from zones of complex terrain. Apparently the fluid was derived from subsurface reservoirs, and the overlying materials collapsed as fluid was released. The channels, unlike the valley networks, probably formed over a considerable span of Martian history. The fluid for carving the channels was most likely water, perhaps with substantial amounts of entrained ice and sediment. Ground ice in Martian permafrost may have provided a source for the immense ancient floods.

Other landforms associated with stream erosion

PLANATION SURFACES

Among the most common landscapes on Earth is that of a low-relief plain cutting across varied rocks and structures. There has been much scientific controversy over the origins of these surfaces. Because genetic implications are so often associated with various names, it seems best to refer to these features as simply planation surfaces.

Figure 24 shows a spectacular planation surface that bevels sandstone cuestas in the James Range in central Australia. Clearly an erosive process cut across rocks of

Figure 24: Planation surface cut across dipping Paleozoic sandstone in the James Range, central Australia.

varying resistance. The rock structure would never have developed such a flat surface unless a lateral erosive process had been at work in the past at a particular base level. Where many beveled cuestas of this sort line up at the same approximate elevation, they define the regional planation surface.

Planation surfaces, such as that shown in Figure 24, are especially common in the ancient, tectonically stable land masses of the Southern Hemisphere. The South African geomorphologist Lester C. King identified several phases of cyclic planation, which he correlated on a global basis. The oldest surfaces he recognized, termed Gondwana, were Mesozoic in age and related to the ancient landmass of Pangaea and its subsequent breakup during the Mesozoic. A younger surface, called the African or Moorland, developed during the Late Cretaceous and Early Cenozoic by the stripping of weathered materials from the ancient Gondwana surfaces. Younger surfaces developed during the Late Tertiary and Pleistocene as incomplete planation at levels below the remnants of the ancient plains.

Piedmonts

Pediments. The portion of a plain adjacent to mountain slopes is known as a piedmont. In desert regions the characteristic faceted slopes of the mountain front result in a pronounced juncture of mountain and piedmont, the piedmont angle. Where piedmonts have experienced extensive erosion, often to a degree that bedrock is exposed, they constitute pediments. There may be a veneer of alluvium over the erosional surface, particularly where soft rocks (*e.g.,* shales) occur on the piedmont. Massive rocks, such as granite, may develop spectacular bare-rock pediments that sharply mark a mountain front.

Peter Kresan

Figure 25: Dissected pediment surfaces on the northeastern flank of Mount Graham, southeastern Arizona. The pediments are mantled with early Pleistocene–late Pliocene alluvium.

Pediments probably develop through a complex of processes, including the backwearing of the front slopes of a mountain, mantling and weathering of the pediment surface, and removal of weathered mantles by fluvial and slope processes. In many cases, the erosional history of the pediment does not allow for the preservation of diagnostic evidence as to its origin. Pediments are most common in areas where tectonism is relatively slow, since rapid uplift increases the capability of streams to deliver sediment to piedmont areas, leading to a dominance of deposition over erosion. In nature, the distinction between depositional piedmont landforms (alluvial fans) and erosional ones (pediments) is often unclear. The history of a piedmont influenced by climatic and tectonic changes is almost certainly to be marked by changes in the relative erosional or depositional character. A common situation is to find ancient pediments that were once mantled with fluvial deposits (they may have constituted fans) and that were subsequently left as relict forms when mountain front streams incised the surface (Figure 25).

The growth of pediments at the expense of the mountain mass results in retreat of the mountain front. For a small mountain range in an area of tectonic stability, the entire range may be eroded. This leaves a dome-like surface composed of the coalesced pediments. Cima Dome in the eastern Mojave Desert of California is an excellent example of this advanced stage of planation.

Dome-like surfaces consisting of coalesced pediments

Pediplain. Where pedimentation occurs over broad regions, the coalesced surface is termed a pediplain. King believed that this process was responsible for many of the ancient planation surfaces of the world. Most geomorphologists, however, consider pedimentation to be a local process at mountain fronts, perhaps capable of generating planation surfaces for an individual mountain range but not uniquely the cause of globally correlated surfaces.

Etchplain. Where deep weathering occurs on a landscape, a dichotomy is set up between the thick regolith of weak, weathered rock and the underlying zone of intact rock. If subsequent erosion removes the weathered regolith, then a new planation surface develops through exposure of the old weathering front. This process often results in the exposure of structurally defined compartments of resistant rock. A subsurface landscape is essentially etched from the rock by deep weathering and subsequent removal of weathered products.

Etchplanation appears to have been especially characteristic of the ancient, stable cratonic areas of Gondwanaland, the supercontinent that many researchers believe once existed in the Southern Hemisphere. Deep weathering, generally tropical laterization, occurred through the Mesozoic and Early Tertiary. Great planation surfaces developed as tectonic factors influenced the periodic removal of weathering products.

Peneplain. The concept of a peneplain (the word meaning "almost a plain") emerged from W.M. Davis' cyclic view of landscape evolution. As rivers and hillslopes reduced relief through the phases of youth, maturity, and old age, explained Davis, the eventual result was a plain of extremely low relief. This plain could only change very slowly, since potential energy for fluvial action was greatly reduced. Such a peneplain, as with any planation surface, could become relict when renewed uplift induced stream incision below its former position on the plain.

Because it is tied genetically to the Davisian theory of landscape development, the concept of peneplains is rarely used in modern geomorphology. There is, however, frequent reference to peneplanation in older literature. For modern applications, it is best to use a purely descriptive term such as planation surface or erosion surface for features that were formerly classified as peneplains.

INSELBERGS

The early German explorers of southern Africa were impressed by immense low-relief plains (planation surfaces) from which isolated highlands rose abruptly. The domed or castlelike highlands were dubbed inselbergs (literally "island mountains" in German). Spectacular examples include Ayers Rock and the Olga Rocks (Figure 26) in central Australia.

Figure 26: Enormous inselbergs towering above the central Australian landscape.
Malcolm S. Kirk—Peter Arnold, Inc.

Inselbergs are relict features. They have maintained their relief as the adjacent surrounding landscape was lowered. C.R. Twidale of Australia demonstrated the role of subsurface weathering in shaping the flanking hillslopes and pediments of granitic inselbergs.

Inselbergs as a type of paleoform

The occurrence of inselbergs implies immense variations in the rates of degradational activity on the land surface. These structures are one of several varieties of landform called paleoforms that can survive with little modification for tens of millions of years. In inselberg landscapes, the active erosional processes are confined to valley sides and valley floors.

Landforms associated with stream deposition

ALLUVIAL FANS AND BAJADAS

Alluvial fans are fan-shaped zones of fluvial deposition that occur where streams emerge from highlands or mountain fronts to adjacent plains. Like pediments, alluvial fans characterize piedmonts, and the two landform types may be considered, respectively, erosional and depositional end members in a continuum of piedmont landscapes. A bajada is a piedmont that consists of multiple coalescing alluvial fans.

Conditions favourable to alluvial fan formation

Tectonically active mountain fronts in desert regions are excellent areas for the development of alluvial fans. Abundant sediment production is achieved from hillslopes that lack vegetative cover, and this sediment is deposited downstream of the point where the stream emerges from the mountain front. Characteristic examples occur in Death Valley in southeastern California (Figure 27). On the western side of the valley, very long fans extend eastward from the Panamint Range. Because of the eastward tilting of the valley, the toes of fans on the eastern side are being buried by the playa sediments of the valley centre. Consequently, the east-side fans are much smaller.

L.K. Lustig—E.B. Inc.

Figure 27: Alluvial fan at the mouth of Copper Canyon, Death Valley, California, an area of internal drainage.

Some of the biggest alluvial fans occur in humid regions. For example, the fan of the Kosi River, which drains the Himalayas, covers an area of 15,000 square kilometres. The Kosi fan has an extremely low gradient. The slope at its apex is one metre per kilometre, and this decreases distally to less than 0.2 metre per kilometre near the Ganges River. The paleo-channels at the fan apex have diffuse patterns that indicate probable braiding when they flowed. Near the fan toe, the abandoned paleo-channels are meandering.

From 1736 to 1964 the Kosi River shifted 110 kilometres from east to west, reworking all the land in between. Unlike alluvial fans of arid regions that show somewhat random shifts of erosion and deposition, the Kosi fan was developed by a progressively shifting channel. The shifting occurred as deposition raised the active portions of the fan, and the river moved to lower terrain on the inactive portions.

Alluvial fans and bajadas may accumulate sediments in tectonic basins over millions of years. The processes that operate on them and the locations of deposition or erosion may vary through time, reflecting changes in climate and tectonism. Processes on alluvial fans include debris flows and mudflows, which are most common at the proximal apex of arid-region fans with mountainous sources of appropriate rock types. Channelized and sheetflood water flows may persist to the distal portions of fans, depending on the climate and infiltration capacity of the fan surface. Fans in humid regions are dominated by water flows, which tend to produce lower-gradient fan surfaces than do debris flows. (For a detailed discussion about the characteristics and formation of alluvial fans, see RIVERS.)

PLAYAS, PANS, AND SALINE FLATS

Playas, pans, and saline flats are among the flattest known landforms. Their slopes are generally less than 0.2 metre per kilometre. When filled with only a few centimetres of water, many kilometres of surface may be inundated. It is the process of inundation that develops and maintains the near-perfect flatness so characteristic of these arid-region landforms.

Relation to flooding

Playas occupy the flat central basins of desert plains. They require interior drainage to a zone where evaporation greatly exceeds inflow. When flooded, a playa lake forms where fine-grained sediment sand salts concentrate. Terminology is quite confused for playas because of many local names. A saline playa may be called a salt flat, salt marsh, salada, salar, salt pan, alkali flat, or salina. A salt-free playa may be termed a clay pan, hardpan, dry lake bed, or alkali flat. In Australia and South Africa small playas are generally referred to as pans. The low-relief plains of these lands contrast with the mountainous deserts of North America, resulting in numerous small pans instead of immense playas. The terms *takyr, sabkha,* and *kavir* are applied in Central Asia, Saudi Arabia, and Iran, respectively.

Saline flats are specialized forms located adjacent to large bodies of water, as, for example, along coasts, lakeshores, and deltas. They flood during storms, either with surface runoff or with surges from the nearby body of water. The saline crusts of saline flats are quite similar to those that develop in playas.

Physical characteristics. Enclosed basins of salt and clay accumulation may originate from numerous causes. Tectonic causes include faulting, as in the East African Rift Valley and Death Valley, and warping, as in Lake Eyre in Australia, Lake Chad in central Africa, and Shaṭṭ al-Jarīd (Chott Djerid) in Tunisia. Wind deflation can produce shallow basins with downwind dunes, as in southeastern Australia. Even very large basins, such as the Qattara Depression of Egypt, have been ascribed to deflation. Local cataclysmic disruptions of drainage (*e.g.,* volcanism, landslides, and meteorite impacts) may produce playas in desert regions.

Modern playa surfaces are not passive receptors of sed-

iment as they were once believed to be. They serve as important sources of dust and salts, which are blown to the surrounding uplands. Complex assemblages of minerals and sediments occur on the playa surfaces. These directly reflect their environment of deposition and may be used to interpret ancient environmental conditions.

Types of playa

Two broad classes of playas may be defined on the basis of past histories. One type develops from the desiccation of a former lake. Sediments in such a playa are primarily lacustrine, rather than derived from modern depositional processes. The second type of playa has no paleolacustrine heritage. Small salt pans in South Africa, called *vokils*, are of this type.

The supply of material, basin depth, and duration of accumulation all contribute to variations in the thickness of playa deposits. Very thick playa sequences may have alternating layers of lacustrine clays and salt beds. The former generally reflect periods of high floodwater runoff into the closed basins, perhaps induced by higher rainfall (a so-called pluvial period). Saline sediments or pure evaporite beds reflect arid climatic phases. The precise climatic interpretation of paleolacustrine playa sequences, however, can be problematic.

Role of flooding and groundwater. Playas affected by occasional surface floods are usually dry. Their surfaces consist of silt and clay deposited by the floodwaters that enter closed basins during the occasional flow events. Salts develop as ponded floodwater in the centre of such a basin gradually evaporates. Water also can be supplied to closed basins by groundwater flow. In basins dominated by groundwater inputs, sediment influxes are minimized, and saline crusts dominate. Moist areas may persist as groundwater flows to the lowest portion of playas. Very large playas may exhibit dry, sediment-dominated sections and moist, salt-dominated sections.

Saline minerals. The salt deposits of a salt pan are zoned like bathtub rings, with less-soluble sulfates and carbonates at the outer margin and highly soluble sodium chloride (table salt) at the centre. The crystallization of these salts can be compared with the evaporation of brine in a dish. The first precipitates from the evaporating brine are calcium carbonate ($CaCO_3$) and magnesium carbonate ($MgCO_3$). These form the outer "bathtub ring." The next ring consists of sulfates of calcium and sodium ($CaSO_4$ and Na_2SO_4, respectively). If sufficient calcium is present, gypsum ($CaSO_4 \cdot 2H_2O$) will form. If less calcium is present, thenardite (Na_2SO_4) and sodium carbonate (Na_2CO_3) may be deposited. The last remaining brines of exceptionally high salinity precipitate highly soluble chlorides of sodium, calcium, magnesium, and potassium.

Zoning of salt deposits in a salt pan

Another kind of zoning occurs in saline playas with respect to the hydration of different minerals. Dehydrated minerals, such as anhydrite ($CaSO_4$), occur on surface areas protected against flooding and in wet saline areas.

Some playas also contain exotic minerals. The Death Valley playa is famous for borate minerals, including borax ($Na_2B_4O_7 \cdot 10H_2O$) and Meyerhofferite ($Ca_2B_6O_{11} \cdot 7H_2O$).

Surface relief and structures. Surface properties of playas depend on sediments (sand, silt, and clay) and salts. Near-surface groundwater may give rise to evaporite crusts formed by rigorous evaporative concentration. Thick salts may form rugged crusts, as at Devil's Golf Course in Death Valley (Figure 28). Regular flooding of evaporative layers may form a very smooth surface, as at Bonneville Salt Flats in Utah. For thick, soluble crusts, dissolution may occur during fluctuations of a high water table. Solution cavities in the crust can produce a salt karst topography.

The muds deposited on playas are subject to drying and shrinking. The amount of volume change varies with the clay minerals present. Smectite clays experience the greatest shrinkage on drying. The presence of salts enhances the effect, since deposition and crystallization of salts in the cracks creates a polygonal network of salt wedges.

Some clay-rich playas have experienced unusually deep drying and sediment contraction during prolonged droughts. Giant desiccation polygons formed under these conditions are as large as 90 metres across. Individual cracks more than one metre wide and 15 metres deep have been observed.

Figure 28: The Devil's Golf Course near Badwater, Death Valley, California. Thick salts on a playa floor may form rugged crusts of this kind.
Stephen J. Krasemann—Peter Arnold, Inc.

Geomorphic evolution. *Impact of climatic change.* Playas, pans, and saline flats are exceptionally sensitive to environmental change. They have been most profoundly influenced by changes in hydrologic regimen induced by the climatic variations of the Quaternary. All have experienced episodes of expanded lake levels in the past. Such predecessors are often called pluvial lakes, thereby implying periods of increased rainfall. It is also possible, however, that lakes could have expanded because of other factors, including increased groundwater inflow and/or decreased evaporation/transpiration.

Paleolake chronologies. Modern geochronologic techniques, such as radiocarbon dating, permit the comparison of fluctuations in the paleolakes that were predecessors to many modern playas. In northern Africa lakes were at a moderately high level from 30,000 to 22,000 years ago. During the maximum cold, dry phase of the last glacial period, from approximately 20,000 to 12,000 years ago, most African lakes were at low levels, and many were dry. From 10,000 to 8,000 years ago, lakes rose to maximum high levels. Lake Chad expanded to the size of the modern Caspian Sea. Small volume lakes, however, are more sensitive to climatic change, recording higher frequency oscillations in the hydrologic balance. Since about 4,000 years ago, the north African lakes have fallen to the range of their modern lows.

Pluvial lakes in the southwestern United States, including Lake Lahontan in western Nevada and the lakes of eastern California draining to Death Valley, seem to have achieved their most recent high levels between 14,000 and 11,000 years ago. The period from 30,000 to 24,000 years ago was marked by low lake levels. Another low was reached in the middle Holocene, about 7,000 years ago. Many of the lakes of the southwestern United States, however, seem to have been not quite in phase with one another.

Effects of wind action. Playas and saline flats are particularly susceptible to wind action. Clays and salts form crusts that curl and flake upon drying. The flakes and curls are readily deflated, and these wind-eroded sediments are then deposited leeward of the playas and saline flats from which they were removed.

In Australia many playas have large transverse crescentic

Clay dunes, or lunettes

foredunes on their leeward side. Because of their silt and clay composition, these features are sometimes called clay dunes. In Australia they are known as lunettes. James M. Bowler, an Australian Quaternary stratigrapher, produced a precise chronology of playa development and associated eolian activity in the desert of western New South Wales, Australia. There, numerous small lakes reached their maximum extent 32,000 years ago, approximately coincident with the age of the first human remains in Australia. From about 26,000 years ago, the lakes fell to low levels. Playas formed roughly 16,000 years ago at a time when eolian activity peaked. High lakes again occurred about 9,000 to 5,000 years ago, but playas were reestablished after that.

The present association of playas, lunettes, and linear dunes in the Australian deserts may imply a causative association. C.R. Twidale proposed that the linear dunes developed as lee-side accumulations of sand trapped by the growth of lunettes. Climatic change is critical to the association. (V.R.B.)

Sand dunes

Sand dunes are accumulations of sand grains shaped into mounds or ridges by the wind under the influence of gravity. They are comparable to other forms that appear when a fluid moves over a loose bed, such as subaqueous "dunes" on the beds of rivers and tidal estuaries and sand waves on the continental shelves beneath shallow seas. Dunes are found wherever loose sand is windblown: in deserts, on beaches, and even on some eroded and abandoned farm fields in semiarid regions, such as northwest India and parts of the southwestern United States. Images of Mars returned by the U.S. Mariner 9 and Viking spacecrafts have shown that dunes are widely distributed on that planet both in craters and in a sand sea surrounding the north polar ice cap.

True dunes must be distinguished from dunes formed in conjunction with vegetation. The latter cover relatively small areas on quiet humid coastlands (see below *Beaches and coastal dunes*) and also occur on the semiarid margins of deserts. True dunes cover much more extensive areas—up to several hundred square kilometres—primarily in great sand seas (ergs), some of which are as big as France or Texas. However, they also occur as small isolated dunes on hard desert surfaces, covering an area of as little as 10 square metres (107 square feet). Areas of gently undulating sandy surfaces with low relief are classified as sand sheets.

Sand sheets

They commonly have a nearly flat or rippled surface of coarse sand grains and are only a few centimetres to metres thick. Minor sand sheets cover only a few square kilometres around the margins of dune fields. A few, such as the Selima Sand Sheet in southwestern Egypt and the northwestern Sudan, are probably almost as extensive as some of the great sand seas.

During the last 2,000,000 years or so the conditions of very low rainfall under which true dunes form expanded beyond the margins of the Sahara and other present-day arid regions into areas that are now more humid. The best evidence for these changes is the presence of sand seas that are immobilized by vegetation. Dunes formed under similar climates in the geologic past and at certain times occupied deserts as extensive as modern ones. Rocks formed by the solidification of ancient sand seas occur, for example, in the walls of the Grand Canyon in the southwestern United States; in the west Midlands of England; and in southern Brazil.

GEOMORPHIC CHARACTERISTICS

An understanding of sand dunes requires a basic knowledge of their sands, the winds, and the interactions of these main elements. These factors will be treated in turn in the following sections.

Sands. Dunes are almost invariably built of particles of sand size. Clay particles are not usually picked up by the wind because of their mutual coherence, and if they are picked up they tend to be lifted high into the air. Only where clays are aggregated into particles of sand size, as on the Gulf Coast of Texas, will they be formed into dunes. Silt is more easily picked up by the wind but is carried away faster than sand, and there are few signs of dunelike bed forms where silt is deposited, for instance as sheets of loess. Particles coarser than sands, such as small pebbles, only form dunelike features when there are strong and persistent winds, as in coastal Peru, and these coarse-grained features are generally known as granule ripples rather than dunes. Larger particles, such as small boulders, can be moved by the wind only on slippery surfaces (*e.g.*, ice or wet saline mud) and never form into dunes.

Common dune sands have median grain diameters between 0.02 and 0.04 centimetre (0.008 and 0.016 inch). The maximum common range is between 0.01 and 0.07 centimetre. Most dune sands are well sorted, and a sample of sand from a dune will usually have particles all of very similar size. The sand on sand sheets, however, is poorly sorted and often bimodal—*i.e.*, it is a mixture of coarse sands, often about 0.06 centimetre in diameter, and much finer sands, as well as particles of intermediate size. Windblown sands, especially the coarser particles, are often rounded and minutely pitted, the latter giving the grains a frosted appearance when seen under a microscope.

Minerals in windblown sand

Most windblown sand on the Earth is composed of quartz. Quartz exists in large quantities in many igneous and metamorphic rocks in crystals of sand size. It tends to accumulate when these rocks are weathered away because it resists chemical breakdown better than most minerals, which are taken away in solution. Most of the great sand seas occur in continental interiors that have been losing soluble material for millions of years; as a consequence, quartzose sandstones are common. These sandstones are eroded by rainwash and stream runoff, processes that are spasmodic but violent in deserts. The eroded products are transported to great interior basins where they are deposited. Such alluvial deposits are the sources of most windblown sand. Quartz also predominates in most coastal dune sands, but there usually are considerable mixtures of other minerals in dunes of this kind.

Dune sands not composed of quartz are rarer but not unknown. Near volcanic eruptions in Hawaii, some western states of the continental United States, and Tanzania, for example, dunes are built of volcanic ash particles. In many arid areas, gypsum crystals of sand size are deposited on the floors of ephemeral lakes as the water dries out; they are then blown like sand to form gypsum dunes. Gypsum dunes occur in the White Sands National Monument in New Mexico, as well as in northern Algeria and southwestern Australia.

Winds. Winds have three sources of variation that are important—namely, direction, velocity, and turbulence. Most of the great deserts are found in the subtropical areas of high atmospheric pressure, where the winds circulate in a clockwise direction in the Northern Hemisphere and a counterclockwise direction in the Southern Hemisphere. The high-pressure systems tend to dip down to the east so that winds are stronger there, a pattern mirrored by the dunes. Poleward of these circulation systems are the zones of eastward moving depressions in which there are generally westerly winds that mold the dunes of the North American and Central Asian deserts and of the northern Sahara. The boundaries between these two circulation systems migrate back and forth seasonally, so that complicated dune patterns are found in the zones of overlap. Only a few deserts, notably the Thar Desert of India and the Sonoran Desert of the American Southwest, are affected by monsoonal wind systems. Some dunes are built by sea breezes and local winds, as in coastal Peru.

The direction of the wind at any one place in the desert is affected by a number of local factors. Winds are particularly channeled around topographical features, such as the Tibesti Massif in the Sahara, so that dunes are affected by different winds on different sides of the obstruction. Winds also can be channeled around the dunes themselves, thereby developing patterns of secondary flow that modify the shapes of the dunes.

Wind velocity patterns

The pattern of wind velocity also is important. Like many natural phenomena, wind velocities have a log-normal distribution: there are a large number of moderate breezes and a diminishing number of increasingly more violent winds. The greatest volumes of sand are probably moved

by unusually strong winds, because the amount of sand moved by wind is a power function (exponential factor) of the wind speed. For example, a 10-kilometre-per-hour wind carries 13 grams per hour (0.39 ounce per hour), a 20-kilometre-per-hour wind carries 274 grams per hour, and a 30-kilometre-per-hour wind carries 1,179 grams per hour. A wind of a particular velocity will move fewer larger than smaller grains. Strong winds often blow from a particular direction, as in the southern Sahara, where the intense winds of sandstorms come predominantly from one direction. Such winds are responsible for the undulations of the sand sheets, because they alone can move coarse sands. Lighter winds blow from several different directions, and the dunes, being of finer sand, are therefore affected by several winds.

The wind is retarded near the surface by friction. Above the ground the wind velocity increases rapidly. The near-surface velocity must rise above a certain threshold value before sand will be picked up, the value depending on the size of the sand grains; for example, a wind of 12 kilometres per hour measured at a height of 10 metres is required to move sands 0.02 centimetre in diameter, and a 21-kilometre-per-hour wind is required to move 0.06-centimetre sands. Once sand movement has been initiated by wind of such velocity, it can be maintained by winds blowing at lower speeds. Because instantaneous wind speeds in eddies can rise well above the average velocity, turbulence also is important, but it is difficult to measure.

FORMATION AND GROWTH OF DUNES

The dune-forming process is complex, particularly where many thousands of dunes have grown side-by-side in sand seas. Yet, an introductory account can be given based on the example of a single dune on a hard desert surface.

Most of the sand carried by the wind moves as a mass of jumping (saltating) grains; coarser particles move slowly along the surface as creep and are kept in motion partly by the bombardment of the saltating grains. Saltating sand bounces more easily off hard surfaces than off soft ones, with the result that more sand can be moved over a pebbly desert surface than over a smooth or soft one. Slight hollows or smoother patches reduce the amount of sand that the wind can carry, and a small sand patch will be initiated. If it is large enough, this patch will attract more sand.

The wind adjusts its velocity gradient on reaching the sand patch; winds above a certain speed decrease their near-surface velocity and deposit sand on the patch. This adjustment takes place over several metres, the sand being deposited over this distance, and a dune is built up. The growth of this dune cannot continue indefinitely. The windward slope is eventually adjusted, so that there is an increase in the near-surface velocity up its face to compensate for the drag imposed by the sandy surface. When this happens, the dune stops growing and there is no net gain or loss of sand.

Angle of repose and the slip face

As the dune grows, the smooth leeward slope steepens until the wind cannot be deflected down sharply enough to follow it. The wind then separates from the surface leaving a "dead zone" in the lee into which falls the sand brought up the windward slope. When this depositional slope is steepened to the angle of repose of dry sand (about 32°), this angle is maintained and the added sand slips down the slope or slip face. When this happens, the dune form is in equilibrium, and the dune moves forward as a whole, sand being eroded from the windward side and deposited on the lee.

If the regional rate of sand flow can be calculated from measurements of wind speed and direction, and if it is assumed that the dune has a simple cross section that migrates forward without change of form, a formula for the rate of movement of a dune that agrees with actual measurements can be derived. In Peru dunes have been observed to move at 30 metres per year; in California rates of 25 metres per year have been measured; and in the al-Khārijah Oases (or Kharga Depression) in southern Egypt dunes have been reported to move 20 to 100 metres per year, depending on dune size (in general, small dunes move faster than large dunes because their smaller cross-sectional area requires less sand to be transported to reconstitute their form one dune-length downwind).

DUNE AND SHEET PATTERNS

If the wind were a homogeneous stream of air blowing from one constant direction, long straight dune ridges oriented at right angles to the wind would result. Most dunes, however, are neither straight nor at right angles to the wind, and this indicates that the winds are not a uniform stream or that they blow from different directions. The fairly uniform geometric shapes of several basic types of dunes can be recognized from desert to desert on Earth, and some of the same types have been identified on Mars as well.

Barchan dunes are common to both the Earth and Mars. These small crescent-shaped sand bodies occur in areas where the regional wind blows consistently from one direction (Figure 29). Their crescentic shape must be due to spatial variations in wind velocity, and the regular repetition of dune shapes and spacings when they are close together indicate that the variations in the wind are also regular. This is a property common to all bed forms. It is thought that the flow of a fluid arranges itself in long spiral vortices parallel to the direction of flow, which, with zones of faster and slower velocities arranged transverse to the flow, gives a regular sinuous pattern on the bed.

Where there is a continuous sand cover, a varied dune pattern results from the pattern of flow. The main forms are transverse ridges composed of alternating crescentic elements, like barchans, facing downwind, and other crescentic elements facing upwind. These enclose between them a regular pattern of small hollows. Superimposed on this are small straight ridges parallel with the flow. These elements form a network pattern that is extremely common in the great sand seas. The dunes commonly reach a height of nearly 200 metres and are spaced hundreds of metres to more than two kilometres apart.

One of the important features of sandy terrains is that their forms occur in a number of distinct sizes. Large features are covered with smaller ones, and the smaller ones are covered with ripples (Figure 30). In most of the larger sand seas there is usually a network pattern of very large dunes known as compound dunes, mega-dunes, or *draa*. These are sometimes arranged parallel to the apparent flow, in long ridges, and occasionally transverse to it in great sand waves. The compound dunes are usually covered with a smaller, secondary dune pattern, and the smaller dunes with ordinary sand ripples in most cases. Within each of the size groups of the hierarchy (ripples, dunes, or compound dunes) there are variations in size depending on the grain size of the sand and wind velocity; for example, whereas most ripples are spaced only a few centimetres apart, "mega-ripples," built in very coarse sand, are spaced almost as far apart as small dunes; and whereas most dunes are about 100 metres apart, the low

undulations of coarse sand on sand sheets are up to 500 metres apart. The relation between sand grain size and the shape of a dune is not, however, one of simple cause and effect, for the relation is not constant in all dunes of a given shape or in all localities.

Some dune forms can be related to variations in the overall wind direction, usually on a seasonal cycle. In some areas, winds from opposed directions blow during different seasons, so that "reversing dunes" are formed, in which the slip faces face first in one direction and then in the other. Distinct dunes are formed around topographic obstructions and in sheltered zones on the lee of small hills into which the sand migrates. If the wind meets a high scarp or large hill massif, a so-called echo dune is deposited on the upwind side separated from the scarp by a rolling eddy of air that keeps a corridor free of sand. Many oases and routeways are found in this kind of corridor. Echo dunes are among the largest dunes in the desert, sometimes reaching a height of more than 400 metres.

FIXED DUNES IN SEMIARID REGIONS

Dunes also form around plants in the desert where groundwater is available for vegetation. The usual dune forms that occur in such instances are isolated mounds around individual plants. These forms are known as coppice dunes, or *nebkha*. Further, in many regions that are now subhumid or humid, one finds areas of older dunes fixed by vegetation, providing undeniable evidence that these regions were once more arid than they are today. On the North American high plains, in Hungary, and in Mongolia, the fixed sands have a cover of rich grassland. In Poland they are covered with coniferous forests. The dune patterns on these fixed sands bear a close resemblance to those in active sand seas, except that their forms are rounded and subdued. (A.Wa./W.J.Br./C.S.Br.)

Glacial landforms

Glacial landforms are the product of flowing ice and meltwater. These landforms are forming today in glaciated areas, such as Greenland, Antarctica, and many of the world's higher mountain ranges. In addition, large expansions of present-day glaciers have recurred during the course of Earth history. At the maximum of the last ice age, which ended about 20,000 to 15,000 years ago, more than 30 percent of the Earth's land surface was covered by ice. Consequently, if they have not been obliterated by other landscape-modifying processes since that time, glacial landforms may still exist in regions that were once glaciated but are now devoid of glaciers.

Periglacial features, which form independently of glaciers, are nonetheless a product of the same cold climate that favours the development of glaciers, and so are treated in this section as well.

GENERAL CONSIDERATIONS

Before describing the different landforms produced by glaciers and their meltwater, it seems useful to briefly discuss the glacial environment and the processes responsible for the formation of such landforms.

Types of glaciers. There are numerous types of glaciers, but it is sufficient here to focus on two broad classes: mountain, or valley, glaciers and continental glaciers, or ice sheets, (including ice caps). For information about other types, see the article ICE AND ICE FORMATIONS.

Valley glaciers and ice sheets

Generally, ice sheets are larger than valley glaciers. The main difference between the two classes, however, is their relationship to the underlying topography. Valley glaciers are rivers of ice usually found in mountainous regions, whose flow patterns are controlled by the high relief in those areas. In map view, many large valley glacier systems, which have numerous tributary glaciers that join to form a large "trunk glacier," resemble the roots of a plant. Pancakelike ice sheets, on the other hand, are continuous over extensive areas and completely bury the underlying landscape beneath hundreds or thousands of metres of ice. Within continental ice sheets, the flow is directed more or less from the centre outward. At the periphery, however, where ice sheets are much thinner, they may be controlled by any substantial relief existing in the area. In this case, their borders may be lobate on a scale of a few kilometres, with tonguelike protrusions called outlet glaciers. Viewed by themselves, these are nearly indistinguishable from the lower reaches of a large valley glacier system. Consequently, many of the landforms produced by valley glaciers and continental ice sheets are similar or virtually identical, though they often differ in magnitude. Nonetheless, each type of glacier produces characteristic features and thus warrants separate discussion.

Glacial erosion. Two processes, internal deformation and basal sliding, are responsible for the movement of glaciers under the influence of gravity (see ICE AND ICE FORMATIONS: *Glaciers*). Glaciers that are cold-based, (*i.e.,* frozen to the ground at their base) move solely by internal deformation of the ice mass. Internal deformation, or strain, results from shear stresses in the ice due to a slope on the surface of the glacier and the weight of the ice. The velocity at the bottom of the glacier is zero and increases upward until it reaches a maximum at the surface. Since there is no relative movement between the ice at the bottom of the glacier and the ground to which it is frozen, it is impossible for any erosion to occur at this interface. Investigators reportedly have found dead lichens emerging at the front of a receding cold-based glacier still attached to the rocks on which they originally grew before being buried for hundreds of years by the glacier during its advance. Although this is an extreme case, it illustrates how little cold-based glaciers may alter a landscape. This situation is rare, however, because few glaciers are entirely or partly cold-based. Cold-based glaciers produce no basal meltwater and therefore no glaciofluvial landforms.

The ice in a warm-based, or temperate, glacier is at the pressure melting point throughout. Since it is not frozen to its substrate, a warm-based glacier generally moves not only by internal strain of the ice mass itself but also by sliding along its base. It is this sliding that enables temperate glaciers to erode their beds and carve landforms. Ice is, however, much softer and has a much lower shear strength than most rocks, and pure ice alone is not capable of substantially eroding anything but unconsolidated sediments. Most temperate glaciers have a basal debris zone from several centimetres to a few metres thick that contains varying amounts of rock debris in transit. In this respect, glaciers are comparable to sandpaper; while the paper itself is too soft to sand wood, the adherent hard grains make it a powerful abrasive system. The analogy ends here, however, for the rock debris found in glaciers is of widely varying sizes—from the finest rock particles to large boulders—and also generally of varied types as it includes the different rocks that a glacier is overriding. For this reason, a glacially abraded surface usually bears many different "tool-marks," from microscopic scratches to gouges centimetres deep and tens of metres long. Over thousands of years glaciers may erode their substrate to

a depth of several tens of metres by this mechanism, producing a variety of streamlined landforms typical of glaciated landscapes.

Glacial plucking

Several other processes of glacial erosion are generally included under the term glacial plucking. This process involves the removal of larger pieces of rock from the glacier bed. Various explanations for this phenomenon have been proposed. Some of the mechanisms suggested are based on differential stresses in the rock caused by ice being forced to flow around bedrock obstacles. These pressures have been shown to be sufficient to fracture solid rock, thus making it available for removal by the ice flowing above it. Other possibilities include the forcing apart of rock by the pressure of crystallization produced beneath the glacier as water derived from the ice refreezes (regelation) or because of temperature fluctuations in cavities under the glacier. Still another possible mechanism involves hydraulic pressures of flowing water known to be present, at least temporarily, under nearly all warm-based glaciers. It is hard to determine which process is dominant because access to the base of active glaciers is rarely possible. Nonetheless, investigators know that larger pieces of rock are plucked from the glacier bed and contribute to the number of abrasive "tools" available to the glacier at its base. Other sources for the rock debris in glacier ice may include rockfalls from steep slopes bordering a glacier or unconsolidated sediments overridden as a glacier advances.

Glacial deposition. Debris in the glacial environment may be deposited directly by the ice (till) or, after reworking, by meltwater streams (outwash). The resulting deposits are termed glacial drift.

As the ice in a valley glacier moves from the area of accumulation to that of ablation, it acts like a conveyor belt, transporting debris located beneath, within, and above the glacier toward its terminus or, in the case of an ice sheet, toward the outer margin. Near the glacier margin where the ice velocity decreases greatly is the zone of deposition. As the ice melts away, the debris that was originally frozen into the ice commonly forms a rocky and/or muddy blanket over the glacier margin. This layer often slides off the ice in the form of mudflows. The resulting deposit is called a flow-till. On the other hand, the debris may be laid down more or less in place as the ice melts away around and beneath it. Such deposits are referred to as ablation till. In many cases, the material located between a moving glacier and its bedrock bed is severely sheared, compressed, and "over-compacted." This type of deposit is called lodgment till. By definition, till is any material laid down directly or reworked by a glacier. Typically, it is a chaotic mixture of rock fragments and boulders in a fine-grained sandy or muddy matrix (non-stratified drift). The exact composition of any particular till, however, depends on the materials available to the glacier at the time of deposition. Thus, there are some tills consisting entirely of lake clays deformed by an overriding glacier. Other tills are composed of river gravels and sands that have been "bulldozed" and striated during a glacial advance. Tills often contain some of the tools that glaciers use to abrade their bed. These rocks and boulders bear striations, grooves, and facets, and characteristic till-stones are commonly shaped like bullets or flat-irons. Till-boulders of a rock type different from the bedrock on which they are deposited are dubbed "erratics." In some cases, erratics with distinctive lithologies can be traced back to their source, enabling investigators to ascertain the direction of ice movement of ice sheets in areas where striations either are absent or are covered by till or vegetation.

Tills

Meltwater deposits, also called glacial outwash, are formed in channels directly beneath the glacier or in lakes and streams in front of its margin. In contrast to till, outwash is generally bedded or laminated (stratified drift), and the individual layers are relatively well sorted according to grain size. In most cases, gravels and boulders in outwash are rounded and do not bear striations or grooves on their surfaces, since these tend to wear off rapidly during stream transport. The grain size of individual deposits depends not only on the availability of different sizes of debris but also on the velocity of the depositing current and the distance from the head of the stream. Larger boulders are deposited by rapidly flowing creeks and rivers close to the glacier margin. Grain size of deposited material decreases with increasing distance from the glacier. The finest fractions, such as clay and silt, may be deposited in glacial lakes or ponds or transported all the way to the ocean.

Finally, it must be stressed that most glacier margins are constantly changing chaotic masses of ice, water, mud, and rocks. Ice-marginal deposits thus are of a highly variable nature over short distances, as is much the case with till and outwash as well.

EROSIONAL LANDFORMS

Small-scale features of glacial erosion. Glacial erosion is caused by two different processes: abrasion and plucking (see above). Nearly all glacially scoured erosional landforms bear the tool-marks of glacial abrasion provided that they have not been removed by subsequent weathering (Figure 31). Even though these marks are not large enough to be called landforms, they constitute an integral part of any glacial landscape and thus warrant description here. The type of mark produced on a surface during glacial erosion depends on the size and shape of the tool, the pressure being applied to it, and the relative hardnesses of the tool and the substrate.

Rock polish. The finest abrasive available to a glacier is the so-called rock flour produced by the constant grinding at the base of the ice. Rock flour acts like jewelers' rouge and produces microscopic scratches, which with time smooth and polish rock surfaces, often to a high lustre.

Striations. These are scratches visible to the naked eye, ranging in size from fractions of a millimetre to a few millimetres deep and a few millimetres to centimetres long. Large striations produced by a single tool may be several centimetres deep and wide and tens of metres long.

Because the striation-cutting tool was dragged across the rock surface by the ice, the long axis of a striation indicates the direction of ice movement in the immediate vicinity of that striation. Determination of the regional direction of movement of former ice sheets, however, requires measuring hundreds of striation directions over an extended area because ice moving close to the base of a glacier is often locally deflected by bedrock obstacles. Even when such a regional study is conducted, additional information is frequently needed in low-relief areas to determine which end of the striations points down-ice toward the former outer margin of the glacier. On an outcrop scale,

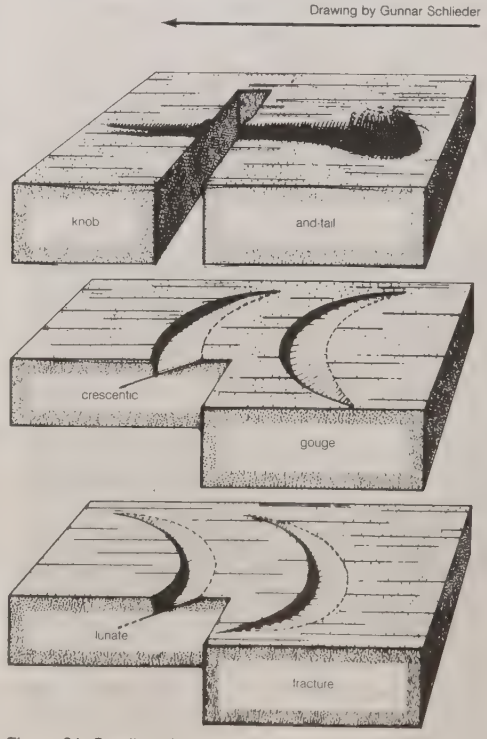

Figure 31: Small-scale features of glacial erosion.

"Chatter marks"

such information can be gathered by studying "chatter marks"—namely, crescentic gouges and lunate fractures. These marks are caused by the glacier dragging a rock or boulder over a hard and brittle rock surface and forming a series of sickle-shaped gouges. Such depressions in the bedrock are steep-sided on their "up-glacier" face and have a lower slope on their down-ice side. Depending on whether the horns of the sickles point up the glacier or down it, the chatter marks are designated crescentic gouges or lunate fractures. Another small-scale feature that allows absolute determination of the direction in which the ice moved is what is termed knob-and-tail. A knob-and-tail is formed during glacial abrasion of rocks that locally contain spots more resistant than the surrounding rock, as, for example, silicified fossils in limestone. After abrasion has been active for some time, the harder parts of the rock form protruding knobs as the softer rock is preferentially eroded away around them. During further erosion, these protrusions protect the softer rock on their lee side and a tail forms there, pointing from the knob to the margin of the glacier. The scale of these features depends primarily on the size of the inhomogeneities in the rock and range from fractions of millimetres to metres.

P-forms and glacial grooves. These features, which extend several to tens of metres in length, are of uncertain origin. P-forms (P for plastic) are smooth-walled, linear depressions which may be straight, curved, or sometimes hairpin-shaped and measure tens of centimetres to metres in width and depth. Their cross sections are often semicircular to parabolic, and their walls are commonly striated parallel to their long axis, indicating that ice once flowed in them. Straight P-forms are frequently called glacial grooves, even though the term is also applied to large striations, which, unlike the P-forms, were cut by a single tool. Some researchers believe that P-forms were not carved directly by the ice but rather were eroded by pressurized mud slurries flowing beneath the glacier.

Erosional landforms of valley glaciers. Many of the world's higher mountain ranges—*e.g.*, the Alps, the North and South American Cordilleras, the Himalayas, and the Southern Alps in New Zealand, as well as the mountains of Norway, including those of Spitsbergen—are partly glaciated today. During segments of the Pleistocene, such glaciers were greatly enlarged and filled most of the valleys with ice, even reaching far beyond the mountain front in certain places. Most scenic alpine landscapes featuring sharp mountain peaks, steep-sided valleys, and innumerable lakes and waterfalls are a product of several periods of glaciation.

Alpine landscapes

Erosion is generally greater than deposition in the upper reaches of a valley glacier, whereas deposition exceeds erosion closer to the terminus. Accordingly, erosional landforms dominate the landscape in the high areas of glaciated mountain ranges.

Cirques, tarns, U-shaped valleys, arêtes, and horns. The heads of most glacial valleys are occupied by one or several cirques (or corries). A cirque is an amphitheatre-shaped hollow with the open end facing down-valley (Figure 32). The back is formed by an arcuate cliff called the headwall. In an ideal cirque, the headwall is semicircular in plan view. This situation, however, is generally found only in cirques cut into flat plateaus. More common are headwalls angular in map view due to irregularities in height along their perimeter. The bottom of many cirques is a shallow basin, which may contain a lake. This basin and the base of the adjoining headwall usually show signs of extensive glacial abrasion and plucking. Even though the exact process of cirque formation is not entirely understood, it seems that the part of the headwall above the glacier retreats by frost shattering and ice wedging (see below *Periglacial landforms*). The rock debris then falls either onto the surface of the glacier or into the bergschrund—a crevasse between the ice at the head of the glacier and the cirque headwall. The rocks on the surface of the glacier are successively buried by snow and incorporated into the ice of the glacier. Because of a downward velocity component in the ice in the accumulation zone, the rocks are eventually moved to the base of the glacier. At that point, these rocks, in addition to the rock debris from the bergschrund, become the tools with which the glacier erodes, striates, and polishes the base of the headwall and the bottom of the cirque.

Bergschrund

During the initial growth and final retreat of a valley glacier, the ice often does not extend beyond the cirque. Such a cirque glacier is probably the main cause for the formation of the basin scoured into the bedrock bottom of many cirques. Sometimes these basins are "over-deepened" several tens of metres and contain lakes called tarns.

In contrast to the situation in a stream valley, all debris falling or sliding off the sides and the headwalls of a glaciated valley is immediately removed by the flowing ice. Moreover, glaciers are generally in contact with a much larger percentage of a valley's cross section than equivalent rivers or creeks. Thus glaciers tend to erode the bases of the valley walls to a much greater extent than do streams. A river only erodes an extremely narrow line along the lowest part of a valley. The slope of the adjacent valley walls depends on the stability of the bedrock and the angle of repose of the weathered rock debris accumulating at the base of and on the valley walls. For this reason, rivers tend to form V-shaped valleys. Glaciers, which inherit V-shaped stream valleys, reshape them drastically by first removing all loose debris along the base of the valley walls and then preferentially eroding the bedrock along the base and lower sidewalls of the valley. In this way, glaciated valleys assume a characteristic parabolic or U-shaped cross profile, with relatively wide and flat bottoms and steep, even vertical sidewalls. By the same process, glaciers tend to narrow the bedrock divides between the upper reaches of neighbouring parallel valleys

Drawing by Gunnar Schlieder

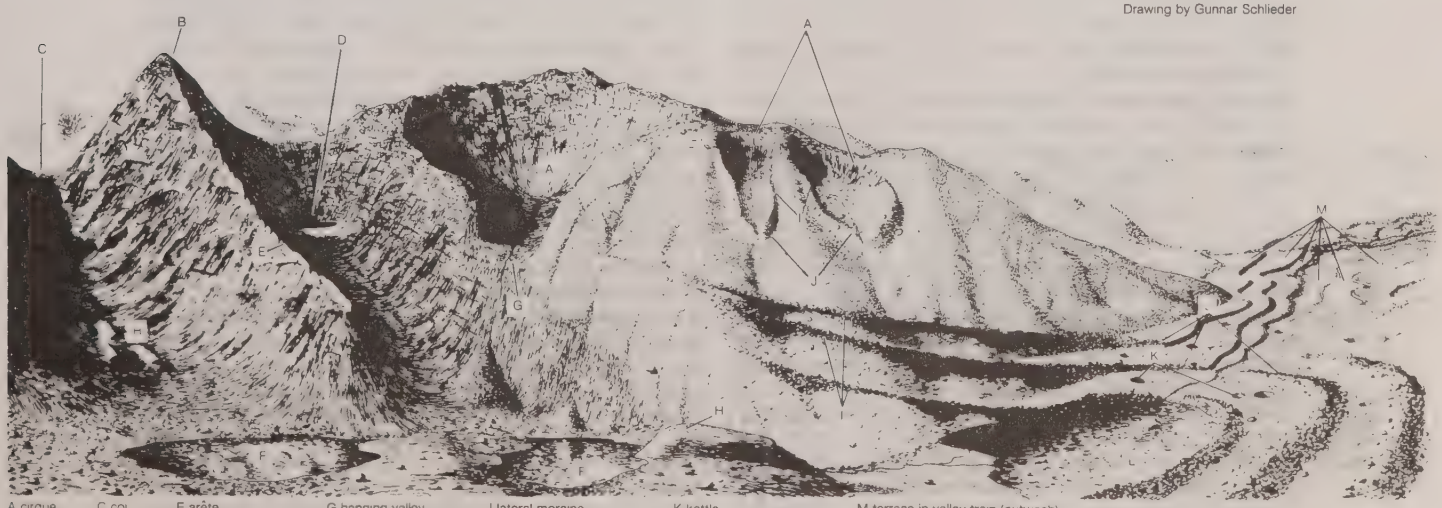

Figure 32: Erosional and depositional landforms of valley glaciation.

to jagged, knife-edge ridges known as arêtes. Arêtes also form between two cirques facing in opposite directions. The low spot, or saddle, in the arête between two cirques is called a col. A higher mountain often has three or more cirques arranged in a radial pattern on its flanks. Headward erosion of these cirques finally leaves only a sharp peak flanked by near vertical headwall cliffs, which are separated by arêtes. Such glacially eroded mountains are termed horns, the most widely known of which is the Matterhorn in the Swiss Alps.

Horns

Hanging valleys. Large valley glacier systems consist of numerous cirques and smaller valley glaciers that feed ice into a large trunk glacier. Because of its greater ice discharge, the trunk glacier has greater erosive capability in its middle and lower reaches than smaller tributary glaciers that join it there. The main valley is therefore eroded more rapidly than the side valleys. With time, the bottom of the main valley becomes lower than the elevation of the tributary valleys. When the ice has retreated, the tributary valleys are left joining the main valley at elevations substantially higher than its bottom. Tributary valleys with such unequal or discordant junctions are called hanging valleys. In extreme cases where a tributary joins the main valley high up in the steep part of the U-shaped trough wall, waterfalls may form after deglaciation, as in Yosemite and Yellowstone national parks in the western United States.

Paternoster lakes. Some glacial valleys have an irregular, longitudinal bedrock profile, with alternating short, steep steps and longer, relatively flat portions. Even though attempts have been made to explain this feature in terms of some inherent characteristic of glacial flow, it seems more likely that differential erodibility of the underlying bedrock is the real cause of the phenomenon. Thus the steps are probably formed by harder or less fractured bedrock, whereas the flatter portions between the steps are underlain by softer or more fractured rocks. In some cases, these softer areas have been excavated by a glacier to form shallow bedrock basins. If several of these basins are occupied by lakes along one glacial trough similar to beads on a string, they are called paternoster lakes.

Roches moutonnées. These structures are bedrock knobs or hills that have a gently inclined, glacially abraded, and streamlined stoss side (*i.e.,* one that faces the direction from which the overriding glacier impinged) and a steep, glacially plucked lee side. They are generally found where jointing or fracturing in the bedrock allows the glacier to pluck the lee side of the obstacle. In plan view, their long axes are often, but not always, aligned with the general direction of ice movement.

Rock drumlins. A feature similar to roches moutonnées, rock drumlins are bedrock knobs or hills completely streamlined, usually with steep stoss sides and gently sloping lee sides. Both roches moutonnées and rock drumlins range in length from several metres to several kilometres and in height from tens of centimetres to hundreds of metres. They are typical of both valley and continental glaciers. The larger ones, however, are restricted to areas of continental glaciation.

Erosional landforms of continental glaciers. In contrast to valley glaciers, which form exclusively in areas of high altitude and relief, continental glaciers, including the great ice sheets of the past, occur in high and middle latitudes in both hemispheres, covering landscapes that range from high alpine mountains to low-lying areas with negligible relief. Therefore, the landforms produced by continental glaciers are more diverse and widespread. Yet, just like valley glaciers, they have an area where erosion is the dominant process and an area close to their margins where net deposition generally occurs. The capacity of a continental glacier to erode its substrate has been a subject of intense debate. All of the areas formerly covered by ice sheets show evidence of areally extensive glacial scouring. The average depth of glacial erosion during the Pleistocene probably did not exceed a few tens of metres, however. This is much less than the deepening of glacial valleys during mountain glaciation. One of the reasons for the apparent limited erosional capacity of continental ice sheets in areas of low relief may be the scarcity of tools available to them in these regions. Rocks cannot fall onto a continental ice sheet in the accumulation zone, because the entire landscape is buried. Thus, all tools must be quarried by the glacier from the underlying bedrock. With time, this task becomes increasingly difficult as bedrock obstacles are abraded and streamlined. Nonetheless, the figure for depth of glacial erosion during the Pleistocene cited above is an average value, and locally several hundreds of metres of bedrock were apparently removed by the great ice sheets. Such enhanced erosion seems concentrated at points where the glaciers flowed from hard, resistant bedrock onto softer rocks or where glacial flow was channelized into outlet glaciers.

Glacial scouring

Streamlined landscape, lakes, and fjords. As a continental glacier expands, it strips the underlying landscape of the soil and debris accumulated at the preglacial surface as a result of weathering. The freshly exposed harder bedrock is then eroded by abrasion and plucking. During this process, bedrock obstacles are shaped into streamlined "whaleback" forms, such as roches moutonnées and rock drumlins (see above). The adjoining valleys are scoured into rock-floored basins with the tools plucked from the lee sides of roches moutonnées. The long axes of the hills and valleys are often preferentially oriented in the direction of ice flow. An area totally composed of smooth whaleback forms and basins is called a streamlined landscape.

Streams cannot erode deep basins because water cannot flow uphill. Glaciers, on the other hand, can flow uphill over obstacles at their base as long as there is a sufficient slope on the upper ice surface pointing in that particular direction. Therefore the great majority of the innumerable lake basins and small depressions in formerly glaciated areas can only be a result of glacial erosion. Many of these lakes, such as the Finger Lakes in the U.S. state of New York, are aligned parallel to the direction of regional ice flow. Other basins seem to be controlled by preglacial drainage systems. Yet, other depressions follow the structure of the bedrock, having been preferentially scoured out of areas underlain by softer or more fractured rock.

A number of the largest freshwater lake basins in the world (*e.g.,* the Great Lakes or the Great Slave Lake and Great Bear Lake in Canada) are situated along the margins of the Precambrian shield of North America. Many researchers believe that glacial erosion was especially effective at these locations because the glaciers could easily abrade the relatively soft sedimentary rocks to the south with hard, resistant crystalline rocks brought from the shield areas that lie to the north. Nonetheless, further research is necessary to determine how much of the deepening of these features can be ascribed to glacial erosion, as opposed to other processes such as tectonic activity or preglacial stream erosion.

Fjords

Fjords are found along some steep, high-relief coastlines where continental glaciers formerly flowed into the sea. They are deep, narrow valleys with U-shaped cross sections that often extend inland for tens or hundreds of kilometres and are now partially drowned by the ocean. These troughs are typical of the Norwegian coast, but they also are found in Canada, Alaska, Iceland, Greenland, Antarctica, New Zealand, and southernmost Chile. The floor and steep walls of fjords show ample evidence of glacial erosion. The long profile of many fjords, including alternating basins and steps, is very similar to that of glaciated valleys. Toward the mouth, fjords may reach great depths, as in the case of Sogn Fjord in southern Norway where the maximum water depth exceeds 1,300 metres. At the mouth of a fjord, however, the floor rises steeply and water depths decrease markedly. At Sogn Fjord the water at this "threshold" is only 150 metres deep, and in many fjords the rock platform is covered by only a few metres of water. The exact origin of fjords is still a matter of debate. While some scientists favour a glacial origin, others believe that much of the relief of fjords is a result of tectonic activity and that glaciers only slightly modified preexisting large valleys. In order to erode Sogn Fjord to its present depth, the glacier occupying it during the maximum of the Pleistocene must have been 1,800 to 1,900 metres thick. Such an ice thickness may seem extreme, but even now, during an interglacial period, the

Skelton Glacier in Antarctica has a maximum thickness of about 1,450 metres. This outlet glacier of the Antarctic ice sheet occupies a trough, which in places is more than one kilometre below sea level and would become a fjord in the event of a large glacial retreat.

DEPOSITIONAL LANDFORMS

Depositional landforms of valley glaciers. *Moraines.* As a glacier moves along a valley, it picks up rock debris from the valley walls and floor, transporting it in, on, or under the ice. As this material reaches the lower parts of the glacier where ablation is dominant, it is concentrated along the glacier margins as more and more debris melts out of the ice. If the position of the glacier margin is constant for an extended amount of time, larger accumulations of glacial debris (till; see above) will form at the glacier margin. In addition, a great deal of material is rapidly flushed through and out of the glacier by meltwater streams flowing under, within, on, and next to the glacier. Part of this streamload is deposited in front of the glacier close to its snout. There, it may mix with material brought by, and melting out from, the glacier as well as with material washed in from other, nonglaciated tributary valleys. If the glacier then advances or readvances after a time of retreat, it will "bulldoze" all the loose material in front of it into a ridge of chaotic debris that closely hugs the shape of the glacier snout. Any such accumulation of till melted out directly from the glacier or piled into a ridge by the glacier is a moraine. Large valley glaciers are capable of forming moraines a few hundred metres high and many hundreds of metres wide. Linear accumulations of till formed immediately in front of or on the lower end of the glacier are end moraines. The moraines formed along the valley slopes next to the side margins of the glacier are termed lateral moraines. During a single glaciation, a glacier may form many such moraine arcs, but all the smaller moraines, which may have been produced during standstills or short advances while the glacier moved forward to its outermost ice position, are generally destroyed as the glacier resumes its advance. The end moraine of largest extent formed by the glacier (which may not be as extensive as the largest ice advance) during a given glaciation is called the terminal moraine of that glaciation. Successively smaller moraines formed during standstills or small readvances as the glacier retreats from the terminal moraine position are recessional moraines.

Terminal and recessional moraines

Flutes. The depositional equivalent of erosional knob-and-tail structures (see above) are known as flutes. Close to the lower margin, some glaciers accumulate so much debris beneath them that they actually glide on a bed of pressurized muddy till. As basal ice flows around a pronounced bedrock knob or a boulder lodged in the substrate, a cavity often forms in the ice on the lee side of the obstacle because of the high viscosity of the ice. Any pressurized muddy paste present under the glacier may then be injected into this cavity and deposited as an elongate tail of till, or flute. The size depends mainly on the size of the obstacle and on the availability of subglacial debris. Flutes vary in height from a few centimetres to tens of metres and in length from tens of centimetres to kilometres, even though very large flutes are generally limited to continental ice sheets.

Depositional landforms of continental glaciers. Many of the deposits of continental ice sheets are very similar to those of valley glaciers. Terminal, end, and recessional moraines are formed by the same process as with valley glaciers (see above), but they can be much larger. Morainic ridges may be laterally continuous for hundreds of kilometres, hundreds of metres high, and several kilometres wide. Since each moraine forms at a discreet position of the ice margin, plots of end moraines on a map of suitable scale allow the reconstruction of ice sheets at varying stages during their retreat.

In addition to linear accumulations of glacial debris, continental glaciers often deposit a more or less continuous, thin (less than 10 metres) sheet of till over large areas, which is called ground moraine. This type of moraine generally has a "hummocky" topography of low relief, with alternating small till mounds and depressions. Swamps or lakes typically occupy the low-lying areas. Flutes (see above) are a common feature found in areas covered by ground moraine.

Another depositional landform associated with continental glaciation is the drumlin, a streamlined, elongate mound of sediment. Such structures often occur in groups of tens or hundreds, which are called drumlin fields. The long axis of individual drumlins is usually aligned parallel to the direction of regional ice flow. In long profile, the stoss side of a drumlin is steeper than the lee side. Some drumlins consist entirely of till, while others have bedrock cores draped with till. The till in many drumlins has been shown to have a "fabric" in which the long axes of the individual rocks and sand grains are aligned parallel to the ice flow over the drumlin. Even though the details of the process are not fully understood, drumlins seem to form subglacially close to the edge of an ice sheet, often directly down-ice from large lake basins overridden by the ice during an advance. The difference between a rock drumlin and a drumlin is that the former is an erosional bedrock knob (see above), whereas the latter is a depositional till feature.

Drumlins

Meltwater deposits. Much of the debris in the glacial environment of both valley and continental glaciers is transported, reworked, and laid down by water. Whereas glaciofluvial deposits are formed by meltwater streams, glaciolacustrine sediments accumulate at the margins and bottoms of glacial lakes and ponds.

Glaciofluvial deposits. The discharge of glacial streams is highly variable, depending on the season, time of day, and cloud cover. Maximum discharges occur during the afternoon on warm, sunny summer days, and minima on cold winter mornings. Beneath or within a glacier, the water flows in tunnels and is generally pressurized during periods of high discharge. In addition to debris washed in from unglaciated highlands adjacent to the glacier, a glacial stream can pick up large amounts of debris along its path at the base of the glacier. For this reason, meltwater streams issuing forth at the snout of a valley glacier or along the margin of an ice sheet are generally laden to transporting capacity with debris. Beyond the glacier margin, the water, which is no longer confined by the walls of the ice tunnel, spreads out and loses some of its velocity. Because of the decreased velocity, the stream must deposit some of its load. As a result, the original stream channel is choked with sediments, and the stream is forced to change its course around the obstacles, often breaking up into many winding and shifting channels separated by sand and gravel bars. The highly variable nature of the sediments laid down by such a braided stream reflects the unstable environment in which they form. Lenses of fine-grained, cross-bedded sands are often interbedded laterally and vertically with stringers of coarse, bouldery gravel. Since the amount of sediment laid down generally decreases with distance from the ice margin, the deposit is often wedge-shaped in cross section, ideally gently sloping off the end moraine formed at that ice position and thinning downstream. The outwash is then said to be "graded to" that particular moraine. In map view, the shape of the deposit depends on the surrounding topography. Where the valleys are deep enough not to be buried by the glaciofluvial sediments, as in most mountainous regions, the resulting elongate, planar deposits are termed valley trains. On the other hand, in low-relief areas the deposits of several ice-marginal streams may merge to form a wide outwash plain, or sandur.

Valley trains and sandurs

If the ice margin stabilizes at a recessional position during glacial retreat, another valley train or sandur may be formed inside of the original one. Because of the downstream thinning of the outwash at any one point in the valley, the recessional deposit will be lower than and inset into the outer, slightly older outwash plain (Figure 33). Flat-topped remnants of the older plain may be left along the valley sides; these are called terraces. Ideally each recessional ice margin has a terrace graded to it, and these structures can be used in addition to moraines to reconstruct the positions of ice margins through time. In some cases where the glacier either never formed moraines or where the moraines were obliterated by the outwash

Figure 33: Landforms and features associated with continental glaciers.
Drawing by Gunnar Schlieder

or postglacial erosion, terraces are the only means of ice margin reconstruction.

Streams that flow over the terminus of a glacier often deposit stratified drift in their channels and in depressions on the ice surface. As the ice melts away, this ice-contact stratified drift slumps and partially collapses to form stagnant ice deposits. Isolated mounds of bedded sands and gravels deposited in this manner are called kames. Kame terraces form in a similar manner but between the lateral margin of a glacier and the valley wall. Glacial geologists sometimes employ the term kame moraine to describe deposits of stratified drift laid down at an ice margin in the arcuate shape of a moraine. Some researchers, however, object to the use of the term moraine in this context because the deposit is not composed of till.

In some cases, streams deposit stratified drift in subglacial or englacial tunnels. As the ice melts away, these sinuous channel deposits may be left as long linear gravel ridges called eskers. Some eskers deposited by the great ice sheets of the Pleistocene can be traced for hundreds of kilometres, even though most esker segments are only a few hundred metres to kilometres long and a few to tens of metres high.

Eskers

Kettles, potholes, or ice pits are steep-sided depressions typical of many glacial and glaciofluvial deposits. Kettles form when till or outwash is deposited around ice blocks that have become separated from the active glacier by ablation. Such "stagnant" ice blocks may persist insulated under a mantle of debris for hundreds of years. When they finally melt, depressions remain in their place, bordered by slumped masses of the surrounding glacial deposits. Many of the lakes in areas of glacial deposition are water-filled kettles and so are called kettle lakes. If a sandur or valley train contains many kettles, it is referred to as a pitted outwash plain.

Glaciolacustrine deposits. Glacial and proglacial lakes are found in a variety of environments and in considerable numbers. Erosional lake basins have already been mentioned, but many lakes are formed as streams are dammed by the ice itself, by glacial deposits, or by a combination of these factors. Any lake that remains at a stable level for an extended period of time (*e.g.,* hundreds or thousands of years) tends to form a perfectly horizontal, flat, terracelike feature along its beach. Such a bench may be formed by wave erosion of the bedrock or glacial sediments that form the margin of the lake, and it is called a wave-cut bench. On the other hand, it may be formed by deposition of sand and gravel from long-shore currents along the margin of the lake, in which case it is referred to as a beach ridge. The width of these shorelines varies from a few metres to several hundred metres. As the lake level is lowered due to the opening of another outlet or downcutting of the spillway, new, lower shorelines may be formed. Most former or existing glacial lakes (*e.g.,* the Great Salt Lake and the Great Lakes in North America) have several such shorelines that can be used both to determine the former size and depth of now-extinct or shrunken lakes and to determine the amount of differential postglacial uplift because they are now tilted slightly from their original horizontal position.

Where a stream enters a standing body of water, it is forced to deposit its bedload. The coarser gravel and sand are laid down directly at the mouth of the stream as successive, steeply inclined foreset beds. The finer, suspended silt and clay can drift a bit farther into the lake, where they are deposited as almost flat-lying bottomset beds. As the sediment builds out farther into the lake (or ocean), the river deposits a thin veneer of subhorizontal gravelly topset beds over the foreset units. Because the foreset–topset complex often has the shape of a triangle with the mouth of the stream at one apex, such a body of sediment is called a delta. Many gravel and sand pits are located in deltas of former glacial lakes.

The flat-lying, fine-grained bottomset beds of many large former glacial lakes filled in and buried all of the preexisting relief and are now exposed, forming perfectly flat lake plains. Cuts into these sediments often reveal rhythmically interbedded silts and clays. Some of these so-called rhythmites have been shown to be the result of seasonal changes in the proglacial environment. During the warmer summer months, the meltwater streams carry silt and clay into the lakes, and the silt settles out of suspension more rapidly than the clay. A thicker, silty summer layer is thus deposited. During the winter, as the surface of the lake freezes and the meltwater discharge into it ceases, the clays contained in the lake water slowly settle out of suspension to form a thin winter clay layer. Such lacustrine deposits with annual silt and clay "couplets" are known as varves.

Lake plains

PERIGLACIAL LANDFORMS

In the cold, or periglacial, areas adjacent to and beyond the limit of glaciers, a zone of intense freeze-thaw activity produces periglacial features and landforms. This happens because of the unique behaviour of water as it changes from the liquid to the solid state. As water freezes, its volume increases about 9 percent and can, if confined in a crack or pore space, exert pressures of about 200,000 kilopascals (29,000 pounds per square inch). This is enough to break the enclosing rock. Thus freezing water can be a powerful agent of physical weathering. If multiple freeze-and-thaw cycles occur, the growth of ice crystals fractures and moves material by means of frost shattering and frost

heaving, respectively. In addition, in permafrost regions (see below) where the ground remains frozen all year, characteristic landforms are formed by perennial ice.

Features associated with intense freeze-thaw activity

Felsenmeers, talus, and rock glaciers. In nature, the tensional strength of most rocks is exceeded by the pressure of water crystallizing in cracks. Thus, repeated freezing and thawing not only forms potholes in poorly constructed roads but also is capable of reducing exposed bedrock outcrops to rubble. Many high peaks are covered with frost-shattered angular rock fragments. A larger area blanketed with such debris is called a felsenmeer, from the German for "sea of rocks." The rock fragments can be transported downslope by flowing water or fall off the cliff from which they were wedged by the ice. Accumulations of this angular debris at the base of steep slopes are known as talus. Owing to the steepness of the valley sides of many glacial troughs, talus is commonly found in formerly glaciated mountain regions. Talus cones are formed when the debris coming from above is channelized on its way to the base of the cliff in rock chutes. As the talus cones of neighbouring chutes grow over time, they may coalesce to form a composite talus apron.

In higher mountain regions, the interior of thick accumulations of talus may remain at temperatures below freezing all year. Rain or meltwater percolating into the interstices between the rocks freezes over time, filling the entire pore space. In some cases, enough ice forms to enable the entire mass of rock and ice to move downhill like a glacier. The resulting massive, lobate, mobile feature is called a rock glacier. Some rock glaciers have been shown to contain pure ice under a thick layer of talus with some interstitial ice. These features may be the final retreat stages of valley glaciers buried under talus.

Rock glaciers

Permafrost, patterned ground, solifluction deposits, and pingos. Permafrost is ground that remains perennially frozen (see ICE AND ICE FORMATIONS: *Permafrost*). It covers about 20–25 percent of the Earth's land surface today. The "active layer" of soil close to the surface of permafrost regions undergoes many seasonal and daily freeze-thaw cycles. The constant change in the volume of water tends to move the coarser particles in the soil to the surface. Further frost heaving arranges the stones and rocks according to their sizes to produce patterned ground. Circular arrangements of the larger rocks are termed stone rings. When neighbouring stone rings coalesce, they form polygonal stone nets. On steeper slopes, stone rings and stone nets are often stretched into stone stripes by slow downhill motion of the soggy active layer of the permafrost. In other areas, patterned ground is formed by vertical or subvertical polygonal cracks, which are initiated in the soil by contraction during extremely cold winters. During the spring thaw of the active layer, water flows into these cracks, freezes, and expands. This process is repeated year after year, and the ice-filled cracks increase in size. The resulting ice wedges are often several metres deep and a few tens of centimetres wide at the top. Along the sides of ice wedges, the soil is deformed and compressed. Because of this disturbance and sediment that may be washed into the crack as the ice melts, relict patterned ground may be preserved during a period of warmer climate long after the permafrost has thawed. Today, relict patterned ground that formed during the last ice age exists more than 1,000 kilometres to the south of the present limit of permafrost.

When the active layer of permafrost moves under the influence of gravity, the process is termed gelifluction. The soft flowing layer is often folded and draped on hillsides and at the base of slopes as solifluction, or gelifluction, lobes.

In some permafrost areas, the ice tends to accommodate the volume increase during freezing by pushing up ice-cored, circular mounds called pingos. These mounds may be several tens of metres high and hundreds of metres in diameter. (E.B.E./Gu.S.)

Pingos

Caves and karst landscape

Caves are natural openings in the Earth large enough for human exploration. Such cavities, also known as caverns, are formed in many types of rock and by many processes. The largest and most common caves are those formed by chemical reaction between circulating groundwater and bedrock composed of limestone or dolomite. These caves, called solution caves, typically constitute a component of what is known as karst terrain. Named after the Karst region of the western Balkan Peninsula extending from Slovenia to Montenegro, karst terrain in general is characterized by a rough and jumbled landscape of bare bedrock ledges, deranged surface drainage, and sinkholes, as well as caves. It should be noted, however, that there is considerable variation among karst areas. Some may have dramatic surface landforms but few caves. By contrast, others may have extensive cave development with little surface expression; for example, the Guadalupe Mountains of New Mexico, the site of Carlsbad Caverns and various other caves, have very few surface karst features.

Association with karst terrain

Karst landscapes are formed by the removal of bedrock (composed in most cases of limestone, dolomite, gypsum, or salt, but in some cases of such normally insoluble rocks as quartzite and granite) in solution through underground routes rather than through surface weathering and surface streams. As a result, much karst drainage is internal. Rainfall flows into closed depressions and down their drains. Further dissolution in the subsurface forms continuous conduits that serve as integrated drains for the rapid movement of underground water. The outlets for the water-carrying conduits often are springs of majestic size. Caves are fragments of such conduit systems, and some of them provide access to active streams. These caves may be completely water-filled; others are dry passages left behind by streams that cut to lower levels. Surface streams flowing from areas underlain by insoluble rock often sink when they reach the border of a karst region. These sinking streams form tributaries of the underground drainage system.

CAVE TYPES

Not all caves are part of karst landscapes. As discussed above, a substantial number of relatively small caves are formed in lava and by the mechanical movement of bedrock. Other caves are formed in glaciers by the melting of ice. Still others are created by the erosive action of water and wind or from the debris of erosive processes; these are sea caves, eolian caves, rock shelters, and talus caves.

Non-solution caves

Glacier caves. These are long tunnels formed near the snouts of glaciers between the glacial ice and the underlying bedrock. Meltwater from the surface of a glacier drains downward through crevasses, which are enlarged to form shafts leading to the base of the glacier. Because the inlet water is slightly above the melting point of ice, it gradually melts the ice as it seeps along the base of the glacier.

Glacier caves may reach lengths of several kilometres. Mature caves of this sort are tubular conduits, often with intricately sculptured walls. Some of them have a branching pattern. The floors of glacier caves usually consist of rock. Most glacier caves can be explored only when the surface is frozen; at other times they are filled with water.

Sea caves, eolian caves, rock shelters, and talus caves. Sea caves are formed by wave action on fractures or other weaknesses in the bedrock of sea cliffs along coastlines. They may be mere crevices in the cliff or roomy chambers. Some can be entered only by boat at low tide, while others, occurring along beaches, can be walked into. A sea cave may have an opening to the surface at its rear that provides access from the top of the cliff. In some cases, the ceiling entrance serves as a blowhole from which water spouts during times of high tide or rough seas. Sea caves rarely are more than a few hundred metres long.

Eolian caves are chambers scoured by wind action. They are common in desert areas where they are formed in massive sandstone cliffs. Wind sweeping around such a cavity erodes the walls, floor, and ceiling, resulting in a bottle-shaped chamber usually of greater diameter than the entrance. Eolian caves are rarely longer than a few tens of metres.

Rock shelters are produced by bedrock erosion in insoluble rocks. A common setting is where a resistant rock such as a sandstone overlies shale or some other relatively weak rock. Surface weathering or stream action wears away the

shale, cutting it back into the hillside. The sandstone is left behind as a roof to the rock shelter. Rock shelters are minor features as caves, but many are important archaeological or historical sites.

Talus caves are openings formed between boulders piled up on mountain slopes. Most of them are very small both in length and in cross section. Some boulder piles, however, do have explorable interconnected "passages" of considerable length. Some of the largest talus caves occur among granite blocks in New York and New England, where integrated systems of passages between boulders have been mapped to lengths of several kilometres.

Solution caves. As previously noted, the largest and most common caves are those formed by dissolution of limestone or dolomite. Limestone is composed mostly of calcium carbonate in the form of the mineral calcite. Dolomite rock consists of calcium magnesium carbonate, the mineral dolomite. Both these carbonate minerals are somewhat soluble in the weak acids formed by carbon dioxide dissolving in groundwater. Water seeping through soils into the bedrock, water collected by sinkholes, and surface streams sinking underground at the margins of karst areas all percolate along fractures in the bedrock and gradually create sizable passages by chemical action. Because the dissolution process takes place deep in the bedrock, it is not necessary that solution caves have entrances. Most entrances are formed by accidental processes such as the downcutting of surface valleys, the collapse of sinkholes, or the emplacement of quarries or road cuts. Accidental processes of passage collapse and passage plugging divide caves into smaller fragments. Because of this, there are many more small caves than large ones. The longest known cave is the Mammoth Cave–Flint Ridge system in south central Kentucky, which had (as of 1989) a surveyed length of 530 kilometres.

Limestone and dolomite caves

Most solution caves form at relatively shallow depths (from a few tens of metres to 1,000 metres) by the action of water rich in carbonic acid (H_2CO_3) derived from recent rainfall. Some solution caves, however, appear to have been formed by deep-seated waters such as oil field brines. Sources of acid other than carbonic acid (*e.g.*, sulfuric acid from the oxidation of sulfide minerals or the oxidation of hydrogen sulfide-bearing fluids) may be the dissolving agent for such caves. According to some investigators, Carlsbad Caverns originated from dissolution with sulfuric acid.

Gypsum rock, composed primarily of calcium sulfate dihydrate (the mineral gypsum), is more soluble than limestone. Outcrops of gypsum rock are found at the land surface in arid regions such as West Texas, western Oklahoma, and eastern New Mexico. Caves formed by the dissolution of gypsum are much like limestone caves in the size, shape, and pattern of their passages. The Optimisticheskaya Cave in Ukraine is the world's longest gypsum cave, with 165 kilometres of passage.

Gypsum and salt caves

Caves also are formed by the dissolution of salt (the mineral halite). Because it is highly soluble in water, salt outcrops at the land surface only in extremely arid regions. Caves in salt closely resemble limestone caves in passage plan and shape. In most cases, salt caves are small, with passage lengths ranging from a few tens of metres to several hundred metres. Good examples of salt caves occur in Mount Sedom in Israel and in eastern Spain.

EVOLUTION AND DEMISE OF SOLUTION CAVES

Compared with most geologic phenomena, caves are transient features of the landscape. They form, evolve, and are destroyed over periods of time ranging from a few tens of thousands to a few million years. It is possible to sketch the "life history" of a single cave passage as the sequence from an initiation phase, a series of three critical thresholds, an enlargement phase, a stagnation phase, and a decay phase (Figure 34).

Initiation phase. Since limestone is an impermeable rock, groundwater moves mainly through mechanical fractures—joint and bedding-plane partings. Because groundwater seeps slowly through these openings, it becomes nearly saturated with dissolved calcium carbonate, particularly deep in the rock mass. As a result, the ability of the water to further dissolve the limestone is limited, and the fractures thus enlarge very slowly. Calculations show that times on the order of 3,000 to 10,000 years are needed to enlarge a fracture from an initial width of 10 to 50 micrometres to pencil-sized openings five to 10 millimetres wide. When a continuous pathway from the water source to the outlet has been enlarged to five to 10 millimetres width, the initiation phase is complete.

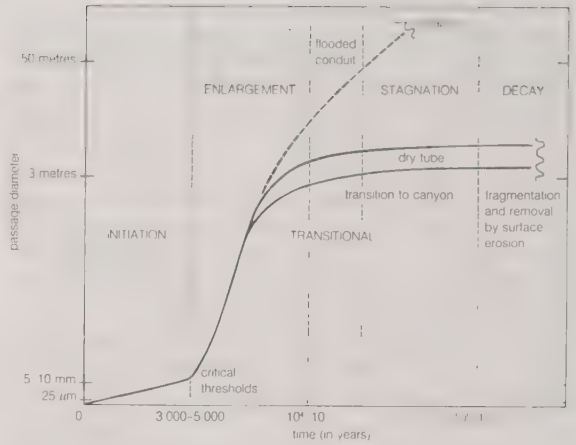

Figure 34: The "life history" of a cave passage.

The five- to 10-millimetre size of the enlarging fracture marks a set of thresholds where new processes come into play. The slow, percolating flow of water is accelerated as the conduit becomes larger, and at the threshold size turbulence appears in the flowing water. The flow pattern is less like percolation through an aquifer and more like flow in a pipe. At the threshold size the opening is large enough and the flow velocities high enough that insoluble sediments can be transported. For the complete development of an underground drainage system, it is necessary that the water-carrying conduits also flush out the soil that washes in through sinkholes, the sediment load of sinking streams, and the insoluble weathering products from the dissolution of the limestone. Another threshold has to do with the rate at which the limestone is dissolved. During the initiation phase when flow velocities are low and the water is nearly saturated, the rate at which limestone is removed is very slow. As velocities increase, unsaturated water moves deep into the bedrock, and the rate of dissolution is greatly increased. The pencil-sized threshold opening marks the boundary between the initial fracture system and the evolving conduit system.

Critical thresholds

Enlargement phase. Once a complete pathway has been opened to threshold size, enlargement takes place rapidly as the conduit provides an efficient route for groundwater flow. Enlargement from threshold size to a full-scale cave passage of one to three metres in diameter can be accomplished in 10,000 to 100,000 years, depending on local geology. During the enlargement phase, the conduit may become completely water-filled, in which case the growing passage takes the form of a circular or elliptical conduit as dissolution acts uniformly on the floor, walls, and ceiling. If the water source feeding the conduit is limited, a time will come when there is not enough water to fill the passage. A free air surface then develops and the dissolution of the ceiling will cease, even though the passage will continue to enlarge through dissolution of the lower walls and floor. This transition from pipe flow to open-channel flow results in a change in passage shape from that of an elliptical tube to that of a canyon. Continued solutional erosion causes the canyon to deepen, resulting in canyon passages 30 to 50 metres high and only one metre or less wide.

Transition from pipe flow to open-channel flow

The fate of a cave passage at the end of the enlargement stage depends on what has been happening elsewhere on the land surface and in the drainage basin. If the passage lies deep below the water table, enlargement will continue until the passage becomes too wide for the ceiling bedrock to support its own weight, and the passage will ultimately collapse. During the time that the cave passage has been enlarging, surface streams have been downcutting their

beds, and the position of base level and the water table is lowered. If the original water source continues to flow through the cave after the transition to canyon shape, the underground canyon can continue to deepen, keeping its gradient adjusted to the lowering surface streams. Sometimes, however, the conduit passages are simply abandoned. Veneers of insoluble sediment that accumulate on the floors of cave passages tend to protect them from solution. As surface streams downcut, the conduits are left behind and the increased hydraulic gradient causes new passages to form at lower levels. In due course, the flow is completely diverted into these new passages, and the original passages remain air-filled and dry above the descending water table.

Stagnation and decay phases. Segments of cave passage abandoned as surface streams downcut can survive for a long time in a stage of stagnation. Truncation of the passages by valley downcutting produces entrances. Caves in the stagnation phase are those most frequently discovered and explored by humans.

Surface erosion continues to dissect the landscape, and hilltops and plateaus are lowered. The underlying cave passages are cut into smaller and smaller fragments. Eventually the denudation of the land surface destroys the last vestiges of the passages, bringing to an end the long history of the cave conduit.

The time scales for the stagnation and decay stages are highly variable, depending on local geologic conditions. Paleomagnetic measurements of the sediments in Mammoth Cave show that the passages at the highest elevations are at least 2,000,000 years old. Studies based on rates of surface weathering in the Appalachian valleys of Pennsylvania indicate that caves at the highest elevation in the residual hills may be 2,000,000 to 3,000,000 years old.

Larger cave systems often have complex patterns of superimposed passages that represent a long history of cave development. The oldest passages, usually but not necessarily those at the highest elevations, may have formed before the glaciations of the Quaternary. The youngest passages may be part of an integrated subsurface drainage system that exists today.

GEOMORPHIC CHARACTERISTICS OF SOLUTION CAVES

Like many other geologic features concealed beneath the earth, caves are difficult to observe. One cannot really see a cave, even though one may have a point-by-point, cross-sectional view as the cave passage is illuminated during exploration. The horizontal ground plans and vertical profiles of caves must be represented by maps. These in turn are constructed from arduous station-to-station surveys by cave explorers.

Variations in cave-passage plans

Some cave-passage plans take the shape of linear, angulate, or sinuous segments of conduit. These are segments of drainage trunk without tributaries. Other cave-passage plans are branchworks. There may be a well-defined "upstream" direction, with tributary passages joining the trunk. Still other passage plans are networks in which passages are laid out in a "city-block" pattern with many intersecting passages and many closed loops. In terms of flow pattern, a single-conduit type of cave forms where much of the original catchment area was on non-karstic borderlands and the sinking stream injected large quantities of water at a single point. Branchwork caves develop where there are multiple inlets, each at the head of one of the tributary branches. Network caves are formed where flows are controlled by diffuse inlets; flow velocities remain low and solutional erosion takes place along all possible joint openings. A network cave is the underground equivalent of a swamp.

Passage cross-sectional shapes reflect the way the water flowed through the cave and the way in which the water dissolved the bedrock. Passages that formed while completely flooded are dissolved away equally on walls, ceilings, and floors. The result is an elliptical tube. In contrast, a flowing stream with a free air surface can dissolve limestone only in its bed. The result is a canyon-shaped passage. In some caves of this type, the walls are nearly vertical and may measure 30 to 50 metres high, even though the passage may only be one metre wide. Other cave passages are very irregular because of the meanderings of the downcutting stream. There is always competition between the hydraulics of flowing water that works to shape passages into smooth, streamlined forms and the control of passage shape by the structural arrangement of joints, fractures, and bedding-plane partings that initiated the passageway. Joint-controlled passages may be high and narrow, sometimes with irregular walls; such a configuration resulted as the passages were enlarged from the initial joint by slowly percolating water. Passages developed primarily along bedding-plane partings may be low and wide. In general, higher flow velocities favour the hydraulic forms, and slow, percolating flows tend to preserve the shapes of the initial mechanical openings.

Most passages of solution caves are nearly horizontal with gentle average slopes toward the outlet springs. If the caves were formed by pressure flow beneath the water table, the passage profile can be irregular, with both downsloping and upsloping segments. Most cave passages are not graded like surface streams. Only in some alpine environments do caves form with steeply sloping passages. Continuous lowering of the level of groundwater circulation often produces tiers of passages stacked one on top of the other, and these need not be interconnected by an explorable cave. Additional mechanisms are needed to explain the vertical arrangement of some caves that may have an internal relief from tens of metres to more than 1,000 metres. Vertical integration is accomplished by some combination of the following: (1) primary vertical solution in the unsaturated zone above the water table during the same time as conduit dissolution below the water table, (2) dissolution of vertical shafts and solution chimneys (see below) in the unsaturated zone at some time after the development of the conduits, or (3) interconnection of existing dry passages by processes of breakdown and collapse.

Vertical integration

Caves in regions of high relief are frequently developed by inputs of water that move by predominantly vertical paths through the unsaturated zone. Such caves often have a stair-step pattern, with vertical pits and shafts offset by short reaches of horizontal passage. Steeply sloping streamways are common. Some caves of the unsaturated zone are simply pits tens to hundreds of metres deep, which show little horizontal development. Others make up complicated cave systems in which many vertical infeeders join to form master streams that descend to base level as waterfalls plunging down pits. One of the largest such systems is the group of caves on the Huautla Plateau in Mexico. The greatest relief from the highest known entrance of the Sistema Huautla to the lowest point of exploration is 1,252 metres in a cave measuring 33.8 kilometres long (1985 data).

Some conduit systems such as those of the Mammoth Cave area and of the Cumberland Plateau of the Appalachian Mountains develop beneath a protective cap of sandstone, shale, and other relatively non-soluble rocks. As the caprock erodes, the underlying limestone is exposed to the runoff water that drains from the remaining area of the plateau. Such runoff water dissolves away the limestone in the unsaturated zone to form solution chimneys and vertical shafts. Solution chimneys develop along vertical fractures or along bedding planes of vertically bedded limestones. In cross section, they tend to be irregular and elongated along the controlling fracture or bedding plane. Solution chimneys follow the fracture and may be offset or descend at steep angles, depending on the pitch of the guiding fracture. Vertical shafts, by contrast, are controlled by the hydraulic forces of freely flowing water. They are often nearly perfect cylinders with circular cross sections. The walls are vertical and cut across the limestone beds with complete disregard for angle or composition of the beds. Vertical shafts and solution chimneys have no direct relation to the conduit system, especially not to the upper dry levels of the system. They sometimes are connected to present-day active horizontal conduits by drain passages. These drains usually are of small cross section and may extend from hundreds of metres or even several kilometres before connecting with the main drainage conduits. In the unsaturated zone, vertical shafts tend to shear

Solution chimneys and vertical shafts

through high-level passages as though they were not there. When vertical shafts and solution chimneys cut through several tiers of overlying horizontal passage, they provide pathways for exploration and integrate the cave system (Figure 35).

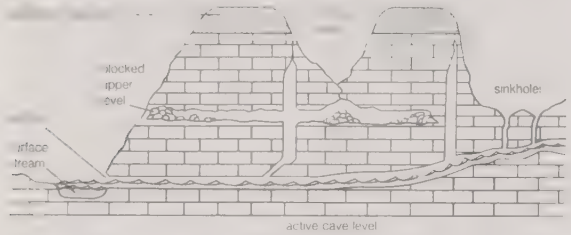

Figure 35: Components of an integrated cave system.

Cave roofs are always in a state of stress. The weight of the ceiling beds causes them to sag slightly, separating the beds along the weaker bedding planes. Each ceiling bed becomes, in effect, a fixed beam spanning the width of the cave passage. There is a strict mechanical relationship between the thickness of a beam, its density, and the width of the span. When the width of the span exceeds a certain critical value, the cave ceiling will collapse under its own weight. Processes such as solution along vertical joints cut the ceiling beams, turning them into cantilevers that have much smaller critical loads. When one ceiling bed falls, support is removed from the bed above and it also may fall. There is thus a process of upward stoping due to ceiling collapse. Upward breakdown and collapse can cause one passage to migrate up into an overlying one.

SOLUTION CAVE FEATURES

Solutional sculpturings. Superimposed on the walls of cave passages are many small solutional sculpturings that record further details of water flow. Pockets of various sizes and kinds are cut back into the walls and ceiling. Some of these have ax-blade shapes and form where water seeping into the cave passage is mixed with the water already in the passage. If the seepage water and the passage water have the correct chemistry, corrosive water forms in the mixing zone and dissolves away the joint-controlled wall and ceiling pockets. Other wall and ceiling pockets are rounded kettle holes or circular cylinders that extend into the solid bedrock of the ceiling with no obvious influence from joints. The ceilings of tropical caves often contain large numbers of the cylindrical cavities, which are used as roosting places by bats. Small secondary channels are carved into the floors or ceilings by flowing water. Floor channels provide evidence of the presence of small later-stage streams that occupied the cave passage after it had been drained of its original flow. Ceiling channels are thought to be the result of upward solutional erosion by cave streams that occurred when the main channel was completely filled with clays, sand, and gravel.

Wall and ceiling pockets

Among the most significant of the solutional sculpturings are the small scooplike depressions known as scallops. Scallops vary in size from a few centimetres to more than one metre. They are asymmetrical in cross section, having a steep wall on the upstream side and a gentler slope on the downstream side. Scallops thus provide information as to the direction of water flow in passages that have been dry for hundreds of thousands of years. The size of a scallop is inversely proportional to the flow velocity of water in the passage. As a consequence, scallops serve not only as paleo-direction indicators but also as paleo-flow meters. Scallops that are a few centimetres wide indicate flow velocities on the order of a few metres per second. The largest scallops, those that are more than one metre wide, indicate flow velocities of a few centimetres per second.

Scallops

The flow velocity of conduit water is sufficient to transport clastic sediment through a cave system. The clastic material is derived from borderlands where it is carried into the karst by sinking streams, from overlying sandstone and shale caprock, from surface soils that are washed underground through sinkholes, and from the insoluble residue of the limestone bedrock. Some of these clastic materials are deposited in caves where they remain as clay, silt, and sand on the cave floors. Some drainage systems carry larger cobble- and boulder-sized materials that are often found in cave streambeds. Most caves have undergone several periods of deposition and excavation, and so remnant beds and pockets of sediment have been left high on cave walls and ledges. These sediments contain iron-bearing magnetic particles, which indicate the position of the Earth's magnetic field at the time when the sediments were deposited. The age of the sedimentary deposits can be determined by measuring the paleomagnetic record in cave sediments and correlating it with the established geomagnetic polarity time scale. Using this method, investigators have ascertained that the age of the sediments in Mammoth Cave is more than 2,000,000 years.

Depositional materials and features. There are three broad categories of sedimentary material found in caves: clastic sediments carried in by streams and infiltrated from the surface; blocks, slabs, and fragments of breakdown derived from the local bedrock; and chemical sediments deposited in the cave by percolating waters. The chemical sediments are the most diverse and are responsible for the decorative beauty of many caves.

The most common of the secondary chemical sediments is calcite, calcium carbonate. There also occurs a less common form of calcium carbonate, the mineral aragonite. The second most common cave mineral is gypsum, calcium sulfate dihydrate. Other carbonate, sulfate, and oxide minerals are occasionally found in caves as well. Many of these require that the cave be associated with ore deposits or with other special geologic environments. For this reason, of the more than 200 mineral species known to occur in caves, only about 20 are found widely.

Deposits of cave minerals occur in many forms, their shapes determined by whether they were deposited by dripping, flowing, or seeping water or in standing pools of water. Collectively, these secondary mineral forms are known as speleothems.

Water emerging from a joint in the cave ceiling hangs for a while as a pendant drop. During this time, a small amount of calcium carbonate is deposited in a ring where the drop is in contact with the ceiling. Then the drop falls, and a new drop takes its place, also depositing a small ring of calcium carbonate. In this manner, an icicle-like speleothem called a stalactite is built up. Stalactites vary in shape from thin strawlike features to massive pendants or drapery-like forms (Figure 36). Stalactites have a central canal that carries water from the feeder joint to the stalactite tip. When the drops fall to the floor of the cave, additional mineral matter is deposited and stalagmites are built up. Stalagmites also take on many forms, from slender broom-handle to mound- and pagoda-like shapes (Figure 36). Stalagmites consist of superimposed caps or layers and do not have a central canal. Stalactites may grow so large that they cannot support their own weight; the broken fragments of large stalactites are sometimes found in caves. Stalagmites are not so restricted and can reach heights of tens of metres. Water flowing along ledges and down walls leaves behind sheets of calcite, which build up a massive deposit known as a flowstone.

Stalactites and stalagmites

Most flowstone deposits are composed of calcite, though other minerals occasionally are present. The calcite is usually coarsely crystalline, densely packed, and coloured various shades of tan, orange, and brown. Some of the pigment is from iron oxides carried into the deposit by the seepage water, but the more common colouring agent is humic substances derived from overlying soils. Humic substances are the organic products of plant decay, which are also responsible for the brown colour of some soils and for the tealike colour of some swamp and lake waters. Calcite speleothems may be pure white but appear milky because of many tiny inclusions of water within the structure.

Flowstone

The calcite in speleothems is derived from the overlying limestone near the bedrock/soil interface. Rainwater infiltrating through the soil absorbs carbon dioxide from the carbon dioxide-rich soil and forms a dilute solution of carbonic acid. When this acid water reaches the base of the soil, it reacts with the calcite in the limestone bedrock and takes some of it into solution. The water continues

Figure 36: Interior of a solution cave decorated with stalactites and stalagmites.
William B White

its downward course through narrow joints and fractures in the unsaturated zone with little further chemical reaction. When the water emerges from the cave roof, carbon dioxide is lost into the cave atmosphere and some of the calcium carbonate is precipitated. The infiltrating water acts as a calcite pump, removing it from the top of the bedrock and redepositing it in the cave below.

Caves provide a very stable environment where temperature and relative humidity may remain constant for thousands of years. The slow growth of crystals is not interrupted, and some speleothems have shapes controlled by the forces of crystal growth rather than by the constraints of dripping and flowing water. Speleothems known as helictites are much like stalactites in that they have a central canal and grow in long tubular forms. They twist and turn in all directions, however, and are not guided by the gravitational pull on pendant water drops. Another variety of speleothem, the anthodite, is a radiating cluster of needlelike crystals. Anthodites are usually composed of aragonite, which has a different habit (*i.e.,* shape of individual crystal grains) than the more common variety of calcium carbonate, calcite. Layered bead or corallike forms occur on cave walls, and complex arrangements of crystals are found in cave pools. Pools of water saturated with calcium carbonate have the remarkable property of surrounding themselves with rimstone dams of precipitated calcite.

Helictites and anthodites

Gypsum and other more water soluble sulfate minerals such as epsomite (magnesium sulfate heptahydrate) and mirabilite (sodium sulfate decahydrate) grow from seepage waters in dry caves. Deposition of the sulfate minerals is due to evaporation of the mineral-bearing solutions. These minerals occur as crusts and in the form of radiating, curving masses of fibrous crystals known as gypsum flowers. Because of their higher solubility, sulfate minerals either do not occur or are destroyed in damp or wet caves.

Gypsum flowers

KARST TOPOGRAPHY

As previously noted, karst landscapes owe their existence to the removal of bedrock in solution and to the development of underground drainage without the development of surface stream valleys. Within these broad constraints, karst landscapes show much variation and are usually described in terms of a dominant landform. Most important with respect to worldwide occurrence are fluviokarst, doline karst, cone and tower karst, and pavement karst.

Common types of karst landscapes

Fluviokarst. In this type of karst landscape, the pattern of surface stream channels and stream valleys are still in evidence, though much of the drainage may be underground. Tributary surface streams may sink underground, and there may be streambeds that carry water only during seasons of high flow or during extreme floods. In addition, the floors of the valleys may be dissected into a sequence of sinkholes.

Consider a normal stream valley that gradually deepens its channel until it cuts into underlying beds of limestone (or dolomite). As the valley cuts deeper and deeper into the carbonate rocks, the stream that flows through it loses water into the limestone through joints and fractures, which begin to enlarge into cave systems. At first, the cave passages will be very small and capable of carrying only a small amount of water. The stream flow on the surface will be reduced but not eliminated. As time passes, the cave passages become larger and capable of carrying more water. There will come a time when they are large enough to take the entire flow of the surface stream during periods of low flow, and during these low-flow periods—typically during summer and fall—the surface stream will run dry. With the passage of more time the cave system continues to enlarge, and more and more of the surface drainage is directed into it. The caves may become large enough to carry even the largest flood flows, and the surface channels will remain dry all year. The surface at this stage is called a dry valley, and it is no longer deepened because no more streams flow through it. Stream banks collapse, channels become overgrown with vegetation, and shallow sinkholes begin to form in the valley floor. Upstream from these "swallow holes" where surface streams are lost to the subsurface, the tributary valleys continue to deepen their channels. These evolve into so-called blind valleys, which end where a stream sinks beneath a cliff. At the top of the cliff is the abandoned floor of the dry valley. In short, fluviokarst is a landscape of active stream valleys, dry valleys, blind valleys, and deranged drainage systems. It is a common type of karst landscape where the soluble carbonate rocks are not as thick as the local relief, so that some parts of the landscape are underlain by carbonate rocks and others by such non-soluble rocks as sandstones or shales.

Doline karst. Such karsts are usually rolling plains that have few surface streams and often no surface valleys. Instead, the landscape is pocked with sinkholes, often tens or hundreds of sinkholes per square kilometre. These sinkholes range from barely discernible shallow swales one to two metres wide to depressions hundreds of metres in depth and one or more kilometres in width. As the sinkholes enlarge, they coalesce to form compound sinks or valley sinks. Some sinkholes form by the dissolution of bedrock at the intersections of joints or fractures. Others result from the collapse of cave roofs, and still others form entirely within the soil. The latter, known as cover collapse sinks and cover subsidence sinks, occur where soils are thick and can be washed into the subsurface by the process of soil piping. Soil loss begins at the bedrock interface. An arched void forms, which migrates upward through the soil until finally the roof collapses abruptly to form the sinkhole. These types of sinkhole constitute a serious land-use problem in karst areas and have been responsible for much property damage when they develop beneath streets, parking lots, houses, and commercial buildings.

Predominance of sinkholes

Cone and tower karst. This variety of karst landscape occurs mainly in tropical areas. Thick limestones are divided into blocks by a grid of joints and fractures. Solution produces deep rugged gorges along the joints and fractures, dividing the mass of limestone into isolated blocks. Because the water dissolving the gorges drains to the subsurface, the gorges are not integrated into a valley system. In some localities, the intervening blocks are rounded into closely spaced conical hills (cone karst). In others, the deepening gorges reach a base level and begin to widen. Sufficient widening may create a lower-level plain from which the remnants of the limestone blocks stand out as isolated, near-vertical towers (tower karst; Figure 37). The cones and towers themselves are sculptured by solution, so that the rock surface is covered by jagged pinnacles and often punctuated by pits and crevices.

Terrain of deep gorges and isolated limestone blocks

Figure 37: Tower karst in Kuei-lin, China.
G Prance—Visuals Unlimited

Pavement karst. This form of karst develops where bare carbonate rocks are exposed to weathering. The initiation of pavement karst is often due to glaciation, which scrapes off soil and weathered rock material to expose the bare bedrock. Accordingly, pavement karsts occur mainly in high latitudes and alpine regions where glacial activity has been prominent. Solutional weathering of the exposed limestone or dolomite is due both to direct rainfall onto the rock surface and to meltwater derived from winter snowpack.

Karren

Pavement karst is decorated with an array of small landforms created by differential solution. These are collectively known as karren. Karren include solutionally widened joints (kluftkarren, or cleftkarren), small runnels (rinnenkarren, or runnelkarren), small residual pinnacles (spitzkarren, or pinnacle karren), and many other forms.

GEOGRAPHIC DISTRIBUTION OF KARST TERRAIN

Approximately 15 percent of the Earth's land surface is karst. The distribution of karst is essentially the same as the distribution of carbonate rocks, which means that karst terrain occurs mostly in the great sedimentary basins of the world. It does not occur in the continental shields underlain by granites and related rocks or in volcanic belts, except in certain islands where massive limestones have been deposited on or around old volcanic cones.

Interior Low Plateaus of the United States

The most extensive karst area of the United States occurs in the limestones of Mississippian age (about 325,000,000 to 345,000,000 years old) of the Interior Low Plateaus. Mostly doline karst with some fluviokarst is found from southern Indiana south along both the east and west flanks of the broad fold of the Cincinnati Arch through eastern and central Kentucky and into Tennessee. Karst also occurs in the limestones of Ordovician age (about 430,000,000 to 500,000,000 years old) that lie exposed on the inner Bluegrass structural dome in Kentucky and on the Nashville Dome in Tennessee. In south central Kentucky is the Mammoth Cave area with the world's longest known cave and many other large cave systems. The Mississippian karst of Kentucky, Tennessee, and Indiana is quite remarkable because the many long cave systems and large areas of doline karst occur in a layer of limestone slightly more than 150 metres thick. Extensive karst also is developed on the limestones that ring the Ozark Dome in Missouri and northern Arkansas. Large caves and areas of fluviokarst and doline karst are found there.

Other notable karst regions of eastern North America include the Appalachians (specifically the Valley and Ridge and Great Valley provinces as well as the Cumberland and Allegheny plateaus) and Florida, where a raised platform of carbonate rocks has large areas of doline karst and extensive internal drainage through a major limestone aquifer. Bermuda and the Bahama Islands also are underlain by young limestones that are highly "karstified." Much of this karst was drowned by rises in sea level at the end of the Pleistocene glaciation. Caves containing stalactites and stalagmites are found at depths of tens of metres below present sea level.

The southwestern United States has very diverse karst regions. For example, West Texas, western Oklahoma, and eastern New Mexico have extensive areas of doline karst in gypsum with many small caves. The Edwards Plateau in south central Texas has a subdued surface karst and numerous small caves. The Capitan reef limestone in southeastern New Mexico contains Carlsbad Caverns and other deep and large volume caves.

The Rocky Mountains have many small areas of alpine karst in Colorado, Wyoming, Utah, and Montana. These are mostly pavement karst with relatively small caves. The Rockies of Canada contain some of that country's longest and deepest caves as well as extensive areas of alpine karst.

The Canadian Rockies

Some of the most spectacular examples of tropical karst occur in Central America and the Caribbean. The islands of the Greater Antilles (Cuba, Jamaica, Hispaniola, and Puerto Rico) are underlain by massive limestones up to 1,000 metres thick. Regions of cone and tower karst have developed in these limestones. The karst of Mexico varies from the streamless, low-relief plain of the Yucatán Peninsula to the high plateaus of the interior with their large dolines and deep vertical caves. Cone and tower karst occurs in the southern part of Mexico and in Belize and Guatemala. Many caves have been reported in Venezuela and Colombia. Little is known of karst in the other countries of South America. Much of the continent is occupied by the Guiana Shield and the Andes Mountains.

Because of its diversity of geologic and climatic settings, Europe has many different types of karst terrain. In the south the Pyrenees exhibit spectacular alpine karst on both the Spanish and French sides. The high-altitude pavement karst contains many deep shafts. The Pierre Saint-Martin System, for example, is 1,342 metres deep and drains a large area of the mountain range. Southern France, notably the Grande Causse, has some of the most spectacular karst in Europe, with deep gorges, numerous caves, and much sculptured limestone. In the Alps are massive folded and faulted limestones and dolomites that underlie alpine karst terrain from France to the Balkan Peninsula. In France the Vercors Plateau is pavement karst featuring many deep caves, including the Berger Shaft—one of the deepest in Europe. The Hölloch Cave, the world's third longest at 133 kilometres, is found in the Swiss Alps. Individual limestone massifs capped with karst plateaus and abounding with deep caves occur in the Austrian Alps.

The Grande Causse of France

Karst is more of a local affair in northern Europe with relatively small caves in Germany and Scandinavia. Some caves have been formed since the Pleistocene glaciation in Norway, as has some high-latitude pavement karst.

England and Ireland have extensive karst areas. The karst of Wales contains the longest caves in England, while the Yorkshire karst has complex vertical caves. Many parts of Ireland are underlain by limestone, and an area called the Burren in County Clare has not only the most caves but also some of the most extensive low-altitude pavement karsts.

Most areas of eastern Europe have karst, but special attention must be paid to the Dinaric Alps along the western edge of the Balkan Peninsula. From Slovenia to Montenegro and from the Adriatic coast 50 kilometres into the interior, the land surface is karst. In addition to areas of fluviokarst, doline karst, and pavement karst, the karst of the Dinaric Alps region is unique for its large number of poljes. These are closed depressions with flat and alluviated bottoms that may be as much as 60 kilometres in diameter. Many of these depressions are elongate parallel to the geologic structure and to the Adriatic coastline. Although isolated poljes have been identified elsewhere, their large numbers in the karst of the Dinaric Alps are attributable to a system of active faults as well as to intense solution activity in nearly 9,000 metres of carbonate rock.

Much of the Mediterranean region—Greece, Turkey, Lebanon, Israel, and parts of the Arabian Peninsula—are arid karst. The region had much more rainfall during the ice ages of the Quaternary, and so karst landscapes developed. Today a combination of arid climatic conditions and overgrazing has reduced many parts of the region to bare rock, an arid-climate form of pavement karst. This is effectively a fossil karst that preserves a record of earlier climatic conditions. The karst regions extend eastward through parts of Iraq to the Zagros Mountains of Iran.

Relatively little karst has been described in Africa. Deep shafts and many caves occur in the Atlas Mountains in the northern part of the continent. Some caves have been described in Zaire, and caves are known in South Africa where sinkhole collapse in the Transvaal Dolomite owing to dewatering by gold mining has been a serious environmental problem.

Asia is a vast region where many types of karst occur. In Russia, important karst areas are found in the Caucasus and Ural mountains. There is an important area of gypsum karst in Ukraine, where very large network caves of gypsum occur. Karst covers about 2,000,000 square kilometres in China, but most renowned is the tower karst of Kweichow, Kwangsi, Yunnan, and Hunan provinces. The Chinese tower karst is developed on folded and faulted rocks unlike most other regions of cone and tower karst, which occur on thick horizontal strata. Isolated vertical-walled towers more than 200 metres high are found along river floodplains in those provinces.

Tower karst of China

Karst regions occur in the South Pacific. In Australia there are caves and some scattered sinkholes along the Nullarbor Plain. Additional karst areas occur in the eastern part of the continent. Many of the Pacific islands are coral reefs that have become karst to varying extents. Extensive cone and tower karst is found in New Guinea, Java, Borneo, and the Malay Peninsula. (W.B.Wh.)

Landforms produced by coastal processes

The coastal environment of the world is made up of a wide variety of landforms manifested in a spectrum of sizes and shapes ranging from gently sloping beaches to high cliffs. The type of landform that is present along any coast is the result of a combination of processes, sediments, and the geology of the coast itself.

Coastal landforms are best considered in two broad categories: erosional and depositional. In fact, the overall nature of any coast may be described in terms of one or the other of these categories. It should be noted, however, that each of the two major landform types may occur on any given reach of coast.

FACTORS AND FORCES IN THE FORMATION OF COASTAL FEATURES

The landforms that develop and persist along the coast are the result of a combination of processes acting upon the sediments and rocks present in the coastal zone. The most prominent of these processes involves waves and the currents that they generate, along with tides. Other factors that significantly affect coastal morphology are climate and gravity.

Waves. The most obvious of all coastal processes is the continual motion of the waves moving toward the beach. Waves vary considerably in size over time at any given location and also vary markedly from place to place. Waves interact with the ocean bottom as they travel into shallow water; as a result, they cause sediment to become temporarily suspended and available for movement by coastal currents. The larger the wave, the deeper the water in which this process takes place and the larger the particle that can be moved. Even small waves that are only a few tens of centimetres high can pick up sand as they reach the shore. Larger waves can move cobbles and rock material as large as boulders.

Suspension of sediment for transport by currents

Generally, small waves cause sediment—usually sand—to be transported toward the coast and to become deposited on the beach. Larger waves, typically during storms, are responsible for the removal of sediment from the coast and its conveyance out into relatively deep water.

Waves erode the bedrock along the coast largely by abrasion. The suspended sediment particles in waves, especially pebbles and larger rock debris, have much the same effect on a surface as sandpaper does. Waves have considerable force and so may break up bedrock simply by impact.

Longshore currents. Waves usually approach the coast at some acute angle rather than exactly parallel to it. Because of this, the waves are bent (or refracted) as they enter shallow water, which in turn generates a current along the shore and parallel to it. Such a current is called a longshore current, and it extends from the shoreline out through the zone of breaking waves. The speed of the current is related to the size of the waves and to their angle of approach. Under rather quiescent conditions, longshore currents move only about 10–30 centimetres per second; however, under stormy conditions they may exceed one metre per second. The combination of waves and longshore current acts to transport large quantities of sediment along the shallow zone adjacent to the shoreline.

Because longshore currents are caused by the approaching and refracting waves, they may move in either direction along the coast, depending on the direction of wave approach. This direction of approach is a result of the wind direction, which is therefore the ultimate factor in determining the direction of longshore currents and the transport of sediment along the shoreline.

Although a longshore current can entrain sediment if it moves fast enough, waves typically cause sediment to be picked up from the bottom, and the longshore current transports it along the coast. In some locations there is quite a large volume of net sediment transport along the coast because of a dominance of one wind direction—and therefore wave direction—over another. This volume may be on the order of 100,000 cubic metres per year. Other locations may experience more of a balance in wave approach, which causes the longshore current and sediment transport in one direction to be nearly balanced by the same process in the other direction.

Rip currents. Another type of coastal current caused by wave activity is the rip current (incorrectly called rip tide in popular usage). As waves move toward the beach, there is some net shoreward transport of water. This leads to a slight but important upward slope of the water level (setup), so that the absolute water level at the shoreline is a few centimetres higher than it is beyond the surf zone. This situation is an unstable one, and water moves seaward through the surf zone in an effort to relieve the instability of the sloping water. The seaward movement is typically confined to narrow pathways. In most cases, rip currents are regularly spaced and flow at speeds of up to several tens of centimetres per second. They can carry sediment and often are recognized by the plume of suspended sediment moving out through the surf zone. In some localities rip currents persist for months at the same site, whereas in others they are quite ephemeral.

Tides. The rise and fall of sea level caused by astronomical conditions is regular and predictable. There is a great range in the magnitude of this daily or semi-daily change in water level. Along some coasts the tidal range is less than 0.5 metre, whereas in the Bay of Fundy in southeastern Canada the maximum tidal range is just over 16 metres. A simple but useful classification of coasts is based solely on tidal range without regard to any other variable. Three categories have been established: micro-tidal (less than two metres), meso-tidal (two to four metres), and macro-tidal (more than four metres). Micro-tidal coasts constitute the largest percentage of the world's coasts, but the other two categories also are widespread.

Tidal ranges

The role of tides in molding coastal landforms is twofold: (1) tidal currents transport large quantities of sediment and may erode bedrock, and (2) the rise and fall of the tide distributes wave energy across a shore zone by changing the depth of water and the position of the shoreline.

Tidal currents transport sediment in the same way that longshore currents do. The speeds necessary to transport the sediment (typically sand) are generated only under certain conditions—usually in inlets, at the mouths of estuaries, or any other place where there is a constriction in the coast through which tidal exchange must take place.

Tidal currents on the open coast, such as along a beach or rocky coast, are not swift enough to transport sediment. The speed of tidal currents in constricted areas, however, may exceed two metres per second, especially in inlets located on a barrier island complex. The speed of these tidal currents is dictated by the volume of water that must pass through the inlet during a given flood or ebb-tide cycle. This may be either six or 12 hours in duration, depending on whether the local situation is semidiurnal (12-hour cycle) or diurnal (24-hour cycle). The volume of water involved, called the tidal prism, is the product of the tidal range and the area of the coastal bay being served by the inlet. This means that though there may be a direct relationship between tidal range and tidal-current speed, it is also possible to have very swift tidal currents on a coast where the tidal range is low if the bay being served by the inlet is quite large. This is a very common situation along the coast of the Gulf of Mexico where the range is typically less than one metre but where there are many large coastal bays.

The rise and fall of the tide along the open coast has an indirect effect on sediment transport, even though currents capable of moving sediment are not present. As the tide comes in and then retreats along a beach or on a rocky coast, it causes the shoreline to move accordingly. This movement of the shoreline changes the zone where waves and longshore currents can do their work. Tidal range in combination with the topography of the coast is quite important in this situation. The greater the tidal range, the more effect this phenomenon has on the coast. The slope of a beach or other coastal landform also is important, however, because a steep cliff provides only a nominal change in the area over which waves and currents can do their work even in a macro-tidal environment. On the other hand, a broad, gently sloping beach or tidal flat may experience a change in the shoreline of as much as one kilometre during a tidal cycle in a macro-tidal setting. Examples of this situation occur in the Bay of Fundy and along the West German coast of the North Sea.

The role of climate

Other factors and processes. Climate is an extremely important factor in the development of coastal landforms. The elements of climate include rainfall, temperature, and wind.

Rainfall is important because it provides runoff in the form of streams and also is a factor in producing and transporting sediment to the coast. This fact gives rise to a marked contrast between the volume and type of sediment carried to the coast in a tropical environment and those in a desert environment.

Temperature is important for two quite different reasons. It is a factor in the physical weathering of sediments and rocks along the coast and in the adjacent drainage basins. This is particularly significant in cold regions where the freezing of water within cracks in rocks causes the rocks to fragment and thereby yield sediment. Some temperate and arctic regions have shore ice up to several months each year. Under these conditions there is no wave impact, and the coast becomes essentially static until the ice thaws or breaks up during severe storms. Such conditions prevail for three to four months along much of the coast of the Great Lakes in North America.

Wind is important primarily because of its relationship to waves. Coasts that experience prolonged and intense winds also experience high wave-energy conditions. Seasonal patterns in both wind direction and intensity can be translated directly into wave conditions. Wind also can be a key factor in directly forming coastal landforms, particularly coastal dunes. The persistence of onshore winds throughout much of the world's coast gives rise to sand dunes in all places where enough sediment is available and where there is a place for it to accumulate.

The effect of gravity

Gravity, too, plays a major role in coastal processes. Not only is it indirectly involved in processes associated with wind and waves but it also is directly involved through downslope movement of sediment and rock as well. This role is particularly evident along shoreline cliffs where waves attack the base of the cliffs and undercut the slope, resulting in the eventual collapse of rocks into the sea or their accumulation as debris at the base of the cliffs.

LANDFORMS OF EROSIONAL COASTS

There are two major types of coastal morphology: one is dominated by erosion and the other by deposition. They exhibit distinctly different landforms, though each type may contain some features of the other. In general, erosional coasts are those with little or no sediment, whereas depositional coasts are characterized by abundant sediment accumulation over the long term. Both temporal and geographic variations may occur in each of these coastal types.

Characteristics of erosional coasts

Erosional coasts typically exhibit high relief and rugged topography. They tend to occur on the leading edge of lithospheric plates, the west coasts of both North and South America being excellent examples (see above *Tectonic landforms*). Glacial activity also may give rise to erosional coasts, as in northern New England and in the Scandinavian countries. Typically, these coasts are dominated by exposed bedrock with steep slopes and high elevations adjacent to the shore. Although these coasts are erosional, the rate of shoreline retreat is slow due to the resistance of bedrock to erosion. The type of rock and its lithification are important factors in the rate of erosion.

Sea cliffs. The most widespread landforms of erosional coasts are sea cliffs (Figure 38). These very steep to vertical bedrock cliffs range from only a few metres high to hundreds of metres above sea level. Their vertical nature is the result of wave-induced erosion near sea level and the subsequent collapse of rocks at higher elevation. Cliffs that extend to the shoreline commonly have a notch cut into them where waves have battered the bedrock surface.

At many coastal locations there is a thin, narrow veneer of sediment forming a beach along the base of sea cliffs. This sediment may consist of sand, but it is more commonly composed of coarse material—cobbles or boulders. Beaches of this kind usually accumulate during relatively low wave-energy conditions and are removed during the stormy season when waves are larger. The coasts of California and Oregon contain many places where this situation prevails. The presence of even a narrow beach along a rocky coast provides the cliffs protection against direct wave attack and slows the rate of erosion.

Peter Arnold, Inc

Figure 38: Erosional coast exemplified by rugged cliffs in San Mateo County, Calif.

Wave-cut platforms. At the base of most cliffs along a rocky coast one finds a flat surface at about the mid-tide elevation. This is a benchlike feature called a wave-cut platform, or wave-cut bench. Such surfaces may measure from a few metres to hundreds of metres wide and extend to the base of the adjacent cliff. They are formed by wave action on the bedrock along the coast. The formation process can take a long time, depending on the type of rock present. The existence of extensive wave-cut platforms thus implies that sea level did not fluctuate during the periods of formation. Multiple platforms of this type along a given reach of coast indicate various positions of sea level.

Sea stacks. Erosion along rocky coasts occurs at various rates and is dependent both on the rock type and on the wave energy at a particular site. As a result of

the above-mentioned conditions, wave-cut platforms may be incomplete, with erosional remnants on the horizontal wave-cut surface. These remnants are called sea stacks, and they provide a spectacular type of coastal landform. Some are many metres high and form isolated pinnacles on the otherwise smooth wave-cut surface. Because erosion is a continual process, these features are not permanent and will eventually be eroded, leaving no trace of their existence.

Isolated rock pinnacles

Sea arches. Another spectacular type of erosional landform is the sea arch, which forms as the result of different rates of erosion typically due to the varied resistence of bedrock. These archways may have an arcuate or rectangular shape, with the opening extending below water level. The height of an arch can be up to tens of metres above sea level (Figure 39).

Figure 39: London Bridge, a sea arch along the southern coast of Victoria, Australia. It rises about 30 metres above sea level.

It is common for sea arches to form when a rocky coast undergoes erosion and a wave-cut platform develops. Continued erosion can result in the collapse of an arch, leaving an isolated sea stack on the platform. Still further erosion removes the stack, and eventually only the wave-cut platform remains adjacent to the eroding coastal cliff.

LANDFORMS OF DEPOSITIONAL COASTS

Characteristics of depositional coasts

Coasts adjacent to the trailing edge of lithospheric plates tend to have widespread coastal plains and low relief. The Atlantic and Gulf coasts of the United States are representative. Such coasts may have numerous estuaries and lagoons with barrier islands or may develop river deltas. They are characterized by an accumulation of a wide range of sediment types and by many varied coastal environments. The sediment is dominated by mud and sand; however, some gravel may be present, especially in the form of shell material.

Depositional coasts may experience erosion at certain times and places due to such factors as storms, depletion of sediment supply, and rising sea level. The latter is a continuing problem as the mean annual temperature of the Earth rises and the ice caps melt. Nevertheless, the overall, long-range tendency along these coasts is that of sediment deposition.

All of the processes discussed at the beginning of this section are in evidence along depositional coasts. Waves, wave-generated currents, and tides significantly influence the development of depositional landforms. In general, waves exert energy that is distributed along the coast essentially parallel to it. This is accomplished by the waves themselves as they strike the shore and also by the longshore currents that move along it. In contrast, tides tend to exert their influence perpendicular to the coast as they flood and ebb. The result is that the landforms that develop along some coasts are due primarily to wave processes while along other coasts they may be due mainly to tidal processes. Some coasts are the result of near equal balance between tide and wave processes. As a consequence, investigators speak of wave-dominated coasts, tide-dominated coasts, and mixed coasts.

Sand beaches and long barrier islands

A wave-dominated coast is one that is characterized by well-developed sand beaches typically formed on long barrier islands with a few widely spaced tidal inlets. The barrier islands tend to be narrow and rather low in elevation. Longshore transport is extensive, and the inlets are often small and unstable. Jetties are commonly placed along the inlet mouths to stabilize them and keep them open for navigation. The Texas and North Carolina coasts of the United States are excellent examples of this coastal type.

Tide-dominated coasts are not as widespread as those dominated by waves. They tend to develop where tidal range is high or where wave energy is low. The result is a coastal morphology that is dominated by funnel-shaped embayments and long sediment bodies oriented essentially perpendicular to the overall coastal trend. Tidal flats, salt marshes, and tidal creeks are extensive. The West German coast of the North Sea is a good example of such a coast.

Mixed coasts are those where both tidal and wave processes exert considerable influence. These coasts characteristically have short stubby barrier islands and numerous tidal inlets. The barriers commonly are wide at one end and narrow at the other. Inlets are fairly stable and have large sediment bodies on both their landward and seaward sides. The Georgia and South Carolina coasts of the United States typify a mixed coast.

Primary large-scale coastal types

General coastal morphology. Depositional coasts can be described in terms of three primary large-scale types: (1) deltas, (2) barrier island/estuarine systems, and (3) strand-plain coasts. The latter two have numerous features in common.

Deltas. An accumulation of sediment at the mouth of a river extending beyond the trend of the adjacent coast is called a delta. Deltas vary greatly in both size and shape, but they all require that more sediment is deposited at the river mouth than can be carried away by coastal processes. A delta also requires a shallow site for accumulation—namely, a gently sloping continental shelf.

The size of a delta is typically related to the size of the river, specifically to its discharge. The shape of a delta, on the other hand, is a result of the interaction of the river with tidal and wave processes along the coast. A classification utilizing each of these three factors as end members provides a good way of considering the variation in delta morphology (Figure 40). River-dominated deltas are those where both wave and tidal current energy on the coast is low and the discharge of water and sediment are little affected by them. The result is an irregularly shaped delta with numerous digitate distributaries. The Mississippi Delta is a good example of a river-dominated delta.

Waves may remove much of the fine deltaic sediment and smooth the outer margin of the delta landform as

From W.E. Galloway, *Deltas, Models for Exploration* (1975); Houston Geological Society

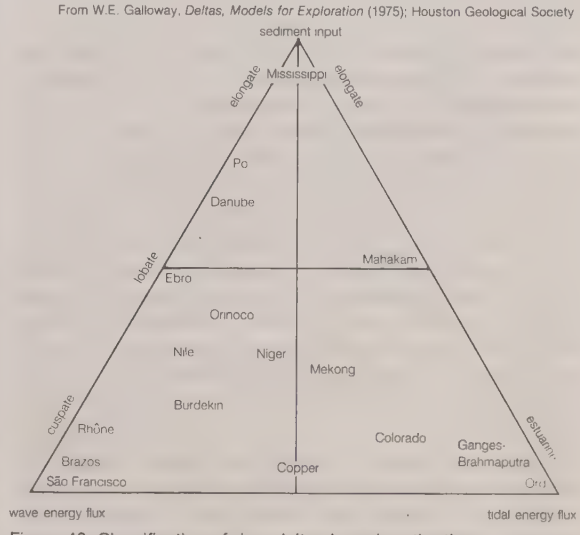

Figure 40: Classification of river deltas based on the three dominant processes that control delta morphology (see text).

well. This results in a smooth, cuspate delta that has few distributaries. The São Francisco Delta in Brazil is such a delta. Some wave-dominated deltas are strongly affected by longshore currents, and the river mouth is diverted markedly along the coast. The Sénégal Delta on the west coast of Africa is an example.

Tide-dominated deltas tend to be developed in wide, funnel-shaped configurations with long sand bodies that fan out from the coast. These sand bodies are oriented with the strong tidal currents of the delta. Tidal flats and salt marshes also are common. The Ord Delta in northern Australia and the Ganges-Brahmaputra Delta in Bangladesh are representative of such a deltaic type.

Barrier island/estuarine systems. Many depositional coasts display a complex of environments and landforms that typically occur together. Irregular coasts have numerous embayments, many of which are fed by streams. Such embayments are called estuaries, and they receive much sediment due to runoff from an adjacent coastal plain. Seaward of the estuaries are elongate barrier islands that generally parallel the shore. Consisting mostly of sand, they are formed primarily by waves and longshore currents. These barrier islands are typically separated from the mainland and may have lagoons, which are long, narrow, coastal bodies of water situated between the barrier and the mainland.

Estuaries

Most barrier islands contain a well-developed beach, coastal dunes, and various environments on their landward side, including tidal flats, marshes, or washover fans. Such coastal barriers are typically interrupted by tidal inlets, which provide circulation between the various coastal bays and the open marine environment. These inlets also are important pathways for organisms that migrate between coastal and open marine areas as well as for pleasure and commercial boat traffic.

Strand-plain coasts. Some wave-dominated coasts do not contain estuaries and have no barrier island system. These coasts, however, do have beaches and dunes, and may even have coastal marshes. The term strand plain has been applied to coasts of this sort. Examples include parts of western Louisiana and eastern Texas. In most respects, they are similar in morphology to barrier islands but lack inlets.

Beaches and coastal dunes. There are several specific landforms representative of coastal environments that are common to each of the three major categories described above. Especially prominent among these are beaches and dunes. They are the primary landforms on barrier islands, strand-plain coasts, and many deltas, particularly the wave-dominated variety.

Beaches. A consideration of the beach must also include the seaward adjacent nearshore environment because the two are intimately related. The nearshore environment extends from the outer limit of the longshore bars that are usually present to the low-tide line. In areas where longshore bars are absent, it can be regarded as coincident with the surf zone. The beach extends from the low-tide line to the distinct change in slope and/or material landward of the unvegetated and active zone of sediment accumulation. It may consist of sand, gravel, or even mud, though sand is the most common beach material.

The beach profile typically can be divided into two distinct parts: (1) the seaward and relatively steep sloping foreshore, which is essentially the intertidal beach, and (2) the landward, nearly horizontal backshore (Figure 41). Beach profiles take on two different appearances, depending on conditions at any given time. During quiescent wave conditions, the beach is said to be accretional, and both the foreshore and backshore are present. During storm conditions, however, the beach experiences erosion, and the result is typically a profile that shows only the seaward sloping foreshore. Because the beach tends to repair itself during nonstorm periods, a cyclic pattern of profile shapes is common.

Foreshore and backshore

The nearshore zone is where waves steepen and break, and then re-form in their passage to the beach, where they break for the last time and surge up the foreshore. Much sediment is transported in this zone, both along the shore and perpendicular to it. During storms the waves tend to be steep, and erosion of the beach occurs with sediment transported offshore. The intervening calmer conditions permit sediment to be transported landward and rebuild the beach. Because wave conditions may change daily, the nature of the profile and the sediment on the foreshore portion of the beach may also change daily. This is the zone of continual change on the beach.

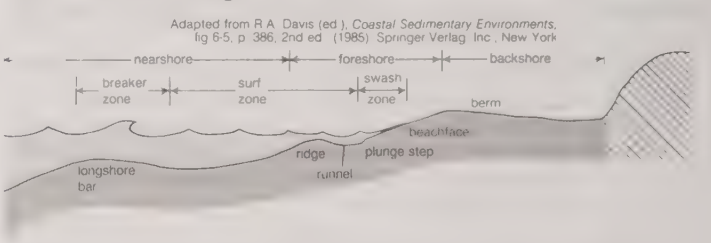

Figure 41: Schematic diagram of a typical beach and nearshore profile.

The backshore of the beach is not subjected to wave activity except during storm conditions. It is actually in the supra-tidal zone—*i.e.*, the zone above high tide where inundation by water is caused not by regular astronomical tides but rather by storm-generated tides. During nonstorm conditions the back-beach is relatively inactive except for wind action, which may move sediment. In most cases, there is an onshore component to the wind, and sediment is carried from the back-beach landward, typically forming dunes. Any obstruction on the back-beach, such as vegetation, pieces of driftwood, fences, or even trash discarded by people, results in wind-blown sand accumulation.

There are variations in beach forms along the shore as well as in those perpendicular to the shore. Most common is the rhythmic topography that is seen along the foreshore. A close look at the shoreline along most beaches will show that it is not straight or gently curved but rather that it displays a regularly undulating surface much like a low-amplitude sine curve. This is seen both on the plan view of the shoreline and the topography of the foreshore. The spacing is regular along a given reach of coast, but it may vary from place to place or from time to time at a given place. At some locations, concentrations of gravel or shells may develop, forming beach cusps (more or less triangular deposits that point seaward) during some wave conditions.

Beach cusps

Although there is a common trend to the beach profile, some variation exists both because of energy conditions and because of the material making up the beach. Generally speaking, a beach that is accumulating sediment and experiencing low-energy conditions tends to have a steep foreshore, whereas the same beach would have a relatively gentle foreshore during storm conditions when erosion is prevalant. The grain size of beach sediment also is an important factor in the slope of the foreshore. In general, the coarser the constituent grains, the steeper the foreshore. Examples include the gravel beaches of New England, as contrasted to the gently sloping sand beaches of the Texas coast.

Coastal dunes. Immediately landward of the beach are commonly found large, linear accumulations of sand known as dunes. (For coverage of dunes in arid and semi-arid regions, see above *Sand dunes.*) They form as the wind carries sediment from the beach in a landward direction and deposits it wherever an obstruction hinders further transport. Sediment supply is the key limiting factor in dune development and is the primary reason why some coastal dunes, such as those on the west Florida peninsula, are quite small, whereas others in such areas as the Texas coast and the Florida panhandle have large dunes.

Small wind-shadow dunes, or coppice mounds, actually may form on the backshore of the beach. If sediment continues to be supplied and beach erosion does not destroy them, these small sand accumulations will become foredunes, the seaward-most line of coastal dunes. It is in this fashion that a coast progrades, or grows seaward. Many barrier-island or strand-plain coasts exhibit numerous, essentially parallel dune ridges testifying to this type of growth.

Foredunes

The sediment in dunes tends to be fine to medium sand

that is quite well sorted. Shell debris or other material is uncommon unless it is the same size or mass as the dune sand. There are various types of vegetation that grow on the dune surface and stabilize it. These grasses and vines often can be seen on the backshore portion of beaches as well. Dunes lacking vegetation are usually active and exhibit various signs of sand mobility. Most widespread are the nearly ubiquitous ripples that cover the dune surface. Large lobes of sand or even an entire dune may also move as wind blows across the dune. This activity results in cross stratification of the dune in large sweeping patterns of wedge-shaped packages of sand. (R.A.D.)

OTHER TYPES OF LANDFORMS

Impact craters

There are features on the continents that have been created by the impact of cosmic bodies (meteorites, asteroids, or comets) on the Earth's surface. In fact, the collision of a Mars-sized body with the Earth early in the history of the solar system may have caused the formation of the Moon and the continents themselves, or rather the ocean/continent dichotomy of the Earth's outer layers.

Impact craters differ from one another principally in terms of size, progressing from small, simple cup-shaped depressions originally with raised rims, through hollows having a central hill (or peak), to those with more complicated central peaks and basins, and finally to multi-ringed basins up to 1,000 kilometres in diameter. The surfaces of the Moon, Mercury, and certain regions of Mars and Venus, as well as most of the satellites of the solar system, are dominated by impact craters. They are much rarer on the Earth, which has about 100 ranging in size from a few tens of metres to 160 kilometres. These have been identified with varying degrees of certainty. The reason for the relative scarcity of impact craters on the Earth is that the processes that formed its surface—largely those of weathering, erosion, and mountain building—have undoubtedly removed the majority of the older structures, such as are observed on the surfaces of the other planets mentioned above.

There is abundant evidence that impact cratering was not only an important surface process in planetary history but that large impact events produced effects that were crustal in scale. The formation of multi-ring basins on the early Moon, for example, is just as important a process in defining the tectonic framework of that body as plate-tectonic phenomena are on the Earth (see above *Tectonic landforms*). Evidence from several planets indicates that the effects of very large-scale impacts go beyond the simple formation of an impact structure and serve to localize increased internal geologic activity over an extended period of geologic time. Although no longer occurring with the same frequency and magnitude as during the early solar system, large-scale impact events have continued to affect the local geology of the inner planets.

Effects of large-scale impact events

The Moon travels through essentially the same orbital space as the Earth. Since the Moon has not been subjected to the surficial geomorphic processes and tectonic activity that prevail on Earth, the lunar surface serves as an invaluable repository of information about the rate and effects of large body impacts that are likely to have occurred on the Earth. Telescopic observations, orbiting remote-sensing spacecraft, and the Apollo manned explorations of the Moon conducted by the United States during the early 1970s have provided the necessary data to establish surface impact rates. These are quite comparable to rates derived independently from astronomical studies for fluxes of asteroidal and cometary objects in near-Earth space. (For details pertaining to this and related questions, see SOLAR SYSTEM: *Asteroids, Comets,* and *Meteoroids, meteors, and meteorites.*)

Some important conclusions for the Earth follow. Asteroidal objects as large as 20 kilometres in diameter probably have struck the planet during the last few billion years, and bodies measuring 10 kilometres across apparently may collide with it every 50,000,000 to 100,000,000 years. Cometary nuclei of similar size may have nearly comparable rates of collision. A 10-kilometre stony object with a density of about three grams per cubic centimetre (0.12 pound per cubic inch) striking the terrestrial surface at a velocity of 25 kilometres per second (15.5 miles per second) would have kinetic energy in excess of 100,000,000 megatons—far greater than that contained in the world's total nuclear arsenal. On land, the impact of such an object would produce a transient crater 60 to 70 kilometres in diameter; the subsequent collapse of the basin walls would result in a final crater having a diameter of possibly 100 to 125 kilometres. Moreover, an impact of this kind would probably exert a planetwide influence on biological evolution because it could trigger mass extinctions of entire species, as perhaps in the case of the dinosaurs 65,000,000 years ago.

GENERAL CHARACTERISTICS OF IMPACT CRATERS ON THE TERRESTRIAL SURFACE

In general, the larger the structure, the longer some of it is preserved but also the less certain the interpretation as an impact structure. Young craters have circular topographic highs around a cup-shaped depression. Older structures may completely lack discernible crater rims, yet they may still retain some degree of circularity, have distinctive internal deformation features, or contain remnants of original rock fragments (breccia) that formed during the impact event. Radial, circular, and annular drainage patterns are common.

Older, more eroded examples of craters are called astroblemes, or more commonly cryptoexplosion structures. The latter designation is a modification of the term cryptovolcanic structure, which is no longer used because investigators have found no evidence for volcanism but much evidence for impact at many such sites. Thus, in a broader sense, an impact crater can be defined as any structure now at or near the surface that contains evidence of a shock-producing impact in which the disturbance by deformation and fragmentation of rock or soil is generally circular and which fades out rapidly in intensity of deformation upon reaching diameter-to-depth ratios of about three to one.

Cryptoexplosion structures

Complex impact structures can be characterized by the presence or absence of peaks and rings, with subdivision into central peak craters, central peak basins, peak ring basins, and multi-ring basins. In general, the sequence from simple structures to multi-ring basins corresponds to increasing diameter or impact energy. The transition diameter of the morphological change from simple to complex form varies between planets probably because of differences in gravity. Most known and suspected terrestrial impact structures more than about three kilometres in diameter contain central uplifts, whereas the smaller ones do not. On the Moon, where gravity is one-sixth that on Earth, craters with central peaks are usually more than 15 to 20 kilometres in diameter. The central peaks make up roughly 10 percent of the width of the total circular deformed zone. Although there is evidence that planetary gravity exerts some control over the value of the transition diameter, it is apparent that parameters such as target rock characteristics also have an effect. This is evident on the Earth where the transition from simple to complex form occurs at four to five kilometres in crystalline rocks but at two to three kilometres in sedimentary rocks. Most of what is known about these various types is based on studies of the lunar surface. (C.R.S.)

FORMATION OF IMPACT CRATERS

Mechanics of the cratering process. The cratering mechanics of simple craters are fairly well understood (Figure 42). On impact, the bulk of the kinetic energy of the projectile is transferred to the planetary surface, where a shock wave is formed. A shock wave is a transient pulse

Generation of shock waves

that moves at velocities higher than those of elastic (seismic or sonic) waves in the same material or medium and that produces an almost instantaneous rise in pressure behind its advancing front. Ahead of this pressure rise, the medium is not yet affected in any way. Behind it, the medium is immediately compressed, leading to a decrease in volume (increase in density) until decompression, or rarefaction, waves allow progressive relaxation. Pressure magnitudes in shock waves exceed the dynamic elastic limits of the transmitting materials. For rocks, this limit falls between 20 and 100 kilobars (1 kilobar equals 1,000 bars, or approximately 14,700 pounds per square inch). By comparison, nuclear explosions and impacts generate pressure waves whose initial amplitudes can reach megabars (1,000,000 bars) in the materials undergoing shock.

An important property of shock waves involves a possible change of phase upon encountering a free surface or another medium of different density and wave propagating characteristics. An initial compression wave will thus be converted to a rarefaction wave, which, if reflected over the previous wave path, can "unload" the state of compression or place the medium under tension (*i.e.,* cause it to stretch or tear). As a shock wave diverges spherically from a point source, its expansion into an ever larger volume also reduces its magnitude, so that the pressure at the moving front continually decreases with increasing radial distance from its source.

Simple craters

Stages of formation. The sequence of events involved in the formation of a simple impact crater (shown schematically in Figure 42) is as follows. Immediately after an incoming object (*e.g.,* a meteorite) strikes the ground, shock waves are imparted both to the rocks and to the object itself. The shock front in the rocks outruns the penetrating meteorite and forms an expanding cavity. The rocks behind the front are strongly compressed and generally are set in radial motion outward from the region of penetration. Depending on the properties of the rocks present, varying fractions of this target material are vaporized, melted, crushed, fragmented, or fractured. Ultimately, different segments of the volume of rock actually excavated are mixed together and dispersed. The initially intense shock attenuates as it diverges outward. The net effect is that the degree of shock damage attributable to compression diminishes with increasing radial distance from the line of penetration. Only a small proportion of the total volume excavated undergoes strong to intense shock pressures, and many of these rocks experience little or no permanent damage.

Excavation process

The actual excavation process requires rarefaction waves. These waves form as the advancing compression waves become isolated, or "detached," from the excavation flow and move onward in the target as a fast-moving shock wave. The shock pressure declines to zero behind the front, but the particle velocity does not. This soon sets up rarefactions that effectively place the rock medium under tension, resulting in a general disruption of the component units. Because these now fragmented pieces were already in motion, many retain enough momentum to carry them forward and out of the developing crater at low angles as ejecta. Fragments that move out of the crater at high angles fall back as crater-filling breccia deposits. Some of the rock material is carried downward without ever leaving the crater to form concentrations of fragmental debris along its base. Beneath these rocks lies a rupture zone consisting of broken and displaced rock that underlies the breccia fill. Compression and rarefaction waves become too weak to efficiently excavate material below the upper boundary of the rupture zone.

Within the rupture zone below the true crater floor and within its walls, the rocks may be folded, faulted, and intricately deformed. Especially in the rim, which marks the outer limit of surface excavation, layered units may be folded over completely to form structures that are similar in complexity to some of the great nappes (folded rock masses moved by thrust faulting) of the Alps. The overturning results when adjacent units below the uplifting free surface are peeled back as they move in close succession. Massive rocks do not fold back but tend to undergo uplift along fractures. All crater-related deformation, however, decreases abruptly away from the junction between the breccia and rupture zone, so beyond this interface the transition from shocked or disturbed rock to ordinary, unmodified country rock is rapid.

During the initial compression stage, materials behind

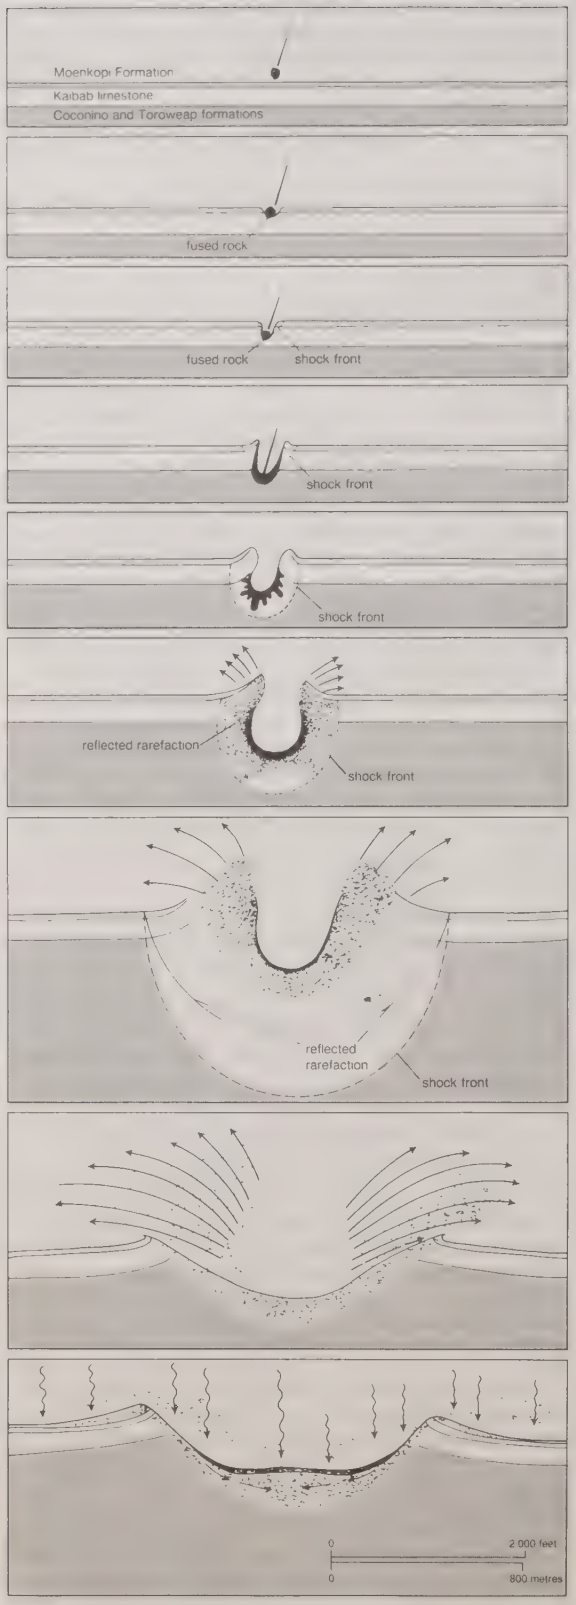

Figure 42: *Stages in the formation of a simple crater.* Shown here is the sequence of events thought to have occurred when an incoming iron meteorite struck the layered rock structures of the Colorado Plateau near Winslow, Ariz., and produced Meteor Crater (see text).

After E.M. Shoemaker in B.M. Middlehurst and G.P. Kuiper (eds.), *The Solar System,* vol. 4 (1963), University of Chicago Press

the shock front experience pressures so high (many hundreds of kilobars) that their dynamic compressive strengths are greatly exceeded. Under these conditions rocks behave much like fluids.

As the spherical shock front advances outward in larger impacts, the compressed shell of material behind it mixes with the meteorite and ejects steadily increasing amounts at the onset of the excavation stage. The complex geometric patterns of particle movements that follow progressive relaxation by rarefaction waves result in the lateral deflection of flowing materials from their earlier radial paths. Below the line of impact, particle movements still proceed mainly downward, but they deviate increasingly sideward until a tangential flow from the crater at low angles dominates the region of the expanding rim. Ejection and crater growth represent a continuous, orderly process involving a steady flow of materials along flow lines. Cratering ceases when stresses become too weak to break up materials.

Variations in structure. In its original state, a simple crater is characterized by a well-defined rim, a bowl-shaped cross section, extensive fallback deposits that thicken toward the centre, and small to moderate amounts (1 to 2 percent) of impact melt concentrated along the central base (Figure 42). Its initial diameter to depth ratio is about five to one. When the crater diameter is greater than four to five kilometres, the rupture zone beneath the central base tends to uplift along shear lines.

Complex craters

Large complex craters have broad, dome-like uplifts, which are sometimes preserved in topographic expression as central peaks (Figure 43). Rocks within this uplifted portion may be strongly shocked and intricately contorted. The mechanism for uplift is related to the size of the impact, properties of the materials, and planetary gravity. It results from the plasticlike rebound of the materials upward under the centre of the impact (Figure 44, uplift stage). Normally, in layered materials the uplift contains stratigraphic units from depths below the general level of the crater base, which indicates the real upward movement of rocks.

Some large craters with central peaks may have been caused by comet impact rather than meteorite impact. When the nucleus of a low-density comet strikes the ground, the dominant energy release remains near the surface. As a result, lateral excavation is more effective than in the case of penetrating iron or stony meteorites.

Generally, complex craters have their breccia-melt deposits in an annular depression between the rim and central peak.

The passage of the transient pressure waves through the rocks and their constituent minerals induces distinctive

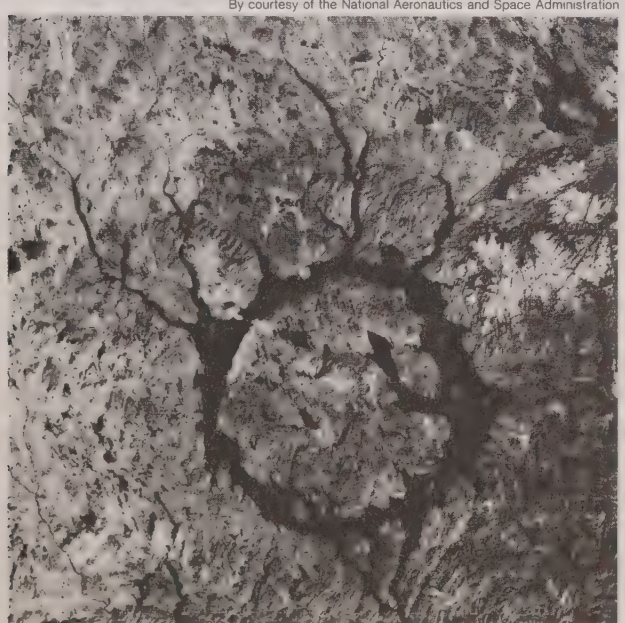

Figure 43: Satellite photograph of the Manicouagan Crater, a complex impact structure, in Quebec, Canada.

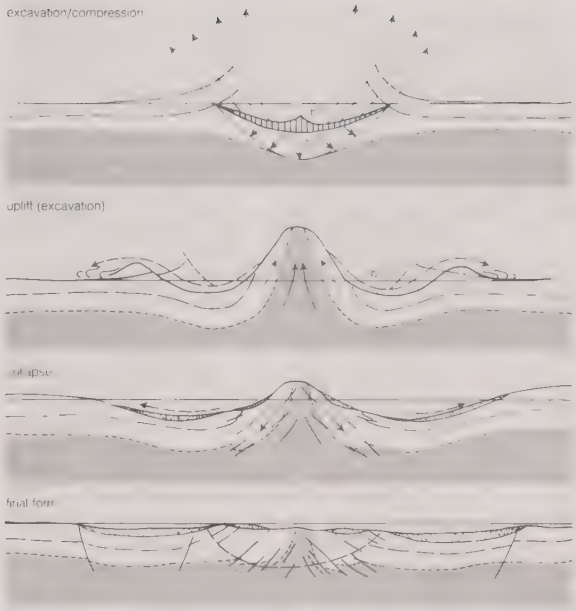

Figure 44: *Stages in the formation of a complex impact crater.* During excavation/compression, the depression created by the penetrating meteorite reaches maximum size, indicated by the extent of the excavated cavity (EC) and transient cavity (TC). The area shown with stripes represents the flow field of fragmented and melted rock that materializes below the level of farthest penetration by the meteorite. The small dashed lines mark the limit of fracturing and brecciation. During uplift, the transient cavity floor undergoes maximum rebound. The resulting dome-like structure subsequently collapses, accompanied by overthrusting and deposition of rock debris in the surrounding depression. In some cases the uplift is preserved as a central peak, while in others it collapses below the original surface level, as shown here.

Adapted from R.A.F. Grieve, P.B. Robertson, and M.R. Dence, "Constraints on the Formation of Ring Impact Structures, Based on Terrestrial Data," *Multi-ring Basins, Proceedings of Lunar and Planetary Sciences* (1981)

effects of very high pressures and temperatures and rapid strain rates that alter their composition and properties. Such effects are described as shock metamorphism. They include the formation of high-pressure polymorphs (different crystalline forms of the same composition) that normally are not stable in the Earth's upper crust; fragmented, fractured, and granulated rock masses; unusual intracrystalline markings; solid-state and selective melting and brief vesiculation (bubbling) caused by pressures ranging up to 500–750 kilobars (comparable to pressures at depths of 1,400–1,800 kilometres within the Earth). The effective temperatures may rise above 2,000° C (3,600° F), and the strain rates are millions of times faster than those operating during mountain building. For these reasons, shock pressures can be determined from rock samples, and the original size of ancient, eroded craters can be estimated. At 20–30 kilobars, cleavage planes in mica start to bend and kink as though folded like layered strata. At higher pressures, more individual mica crystals begin to become distorted, and the intensity of deformation increases in all flakes thus affected. When the shock pressures in the passing waves exceed values of 50–75 kilobars (the dynamic elastic limit of many granitic rocks), changes unknown even in equivalent rock types buried deep within the crust begin to appear.

Shock metamorphism

Another such change is the development of shatter cones. These are peculiar external fracture surfaces in which close-spaced "grooves" seemingly radiate outward from the apex of a cone somewhat like the hair of a horse's tail. Many such cones usually cluster together. Most have apexes that point in a common direction, which, when separate cone-bearing layers are rotated to their original position by photographic analysis, converge toward a single origin that appropriately coincides with the explosion centre of the initial impact. In 1947 Robert S. Dietz of the United States proposed that these features were indicative of impact—*i.e.*, that they originated from shock waves. Subsequent research has proved this hypothesis to be correct.

Shatter cones

In quartz grains, sets of lamellae-like planes form within crystals over a pressure range from about 100 to 400 kilobars. These planar features presumably result from the crushing or slipping of crystal portions along preferred planes of weakness as the grains are compressed rapidly into much smaller volumes. In the higher pressure ranges over which the quartz planar features are produced, high-pressure forms of silica called coesite and stishovite, develop. Other shock-induced polymorphic transformations, as, for example, diamond from other forms of carbon, have been discovered in impact structures.

At still higher pressures (450–600 kilobars), the effect is one of rapidly rising temperature from the conversion of mechanical to thermal energy that leads first to incipient melting of individual grains and then eventually to general melting and variable mixing of the whole rock material.

Transformation of rock material

The net result is the formation of a crater and the transformation of some of the local rocks into impact lithologies: impact melt rocks, shocked breccias (fragmented rocks), and deformed rocks. Evidence from rock samples returned from the lunar highlands, 90 percent of which are of impact origin, suggests that impact lithologies were important geologic constituents of the early crusts of all the inner planets of the solar system. (N.M.S./C.R.S.)

POPULATION OF TERRESTRIAL IMPACT CRATERS

It has been estimated that over the past billion years the land surface of the Earth has been subjected to about 130,000 impacts that have produced craters one kilometre or more in diameter. For the reasons mentioned above, there simply remains no record of most of these impacts. Approximately 100 major craters have been identified worldwide. Numerous small craters have been detected as well. Some are concentrated in clusters and are so small that they cannot be considered landforms. Various small craters also have been associated with specific meteorites.

Terrestrial impact craters range in age from Precambrian to Recent, but the record is heavily biased toward the Recent (see above). Examples of simple bowl-shaped craters, complex central peak structures, central peak basins, and peak-ring basins have been found on the Earth. Examples of multi-ring basins are rare, however. This is a result of the relatively young surface of the Earth and the sharp decrease in the number of impacting bodies in recent geologic time, as compared with the period when large multi-ring basins were formed on the Moon. Based on the lunar record scaled to terrestrial conditions, the Earth, which is more than 4,000,000,000 years old, may have had 25 to 50 basins larger than 1,000 kilometres in diameter. It is possible that the Sudbury crater in Ontario, Canada, and the Vredefort crater in South Africa, both of which measure about 140 kilometres across, originally had a multi-ring form. They both, however, are Precambrian in age and are highly degraded or modified.

Scarcity of multi-ring basins on the Earth

Possibly the best candidates for a well-preserved, multi-ring structure on Earth are the Popigai crater in the Soviet Union, which measures roughly 100 kilometres in diameter and apparently has three rings in the crystalline rocks of its floor; or the Acraman crater in South Australia, which seems to have an inner depressed area about 30 kilometres in diameter, an intermediate depression or ring approximately 90 kilometres in diameter, and possibly an outer ring about 160 kilometres in diameter. Also, investigators have located what appears to be a large crater with central peaks in Wilkes Land, Antarctica. This depression is more than 848 metres deep and 243 kilometres across. (C.R.S.)

Biogenic landforms

Topographic features that can be attributed to the activity of organisms are diverse in both kind and scale. Organisms contribute to the genesis of most topography involving rock weathering; they play an auxiliary role, as demonstrated by bacterial and lichen activity, the effects of root wedging, and solutional erosion made possible by humic acid produced by rapid organic decay. The latter is responsible for much tropical karst (see above *Caves and karst landscape*).

On an entirely different level are features that constitute what may be termed micro topography. Some of these are produced by individual creatures or groups of such creatures, as, for example, the cylindrical mud towers that stand 40–50 centimetres high atop crayfish burrows in the southern part of the United States; badger and bear den burrows; elephant waterholes on the veld (grasslands of Africa); and quarries and open-pit mines dug by humans. Other topographic features are attributable to colonial organisms. In various parts of the world such as the semiarid plains of the Western Sahara, colonies of termites build large conical mounds that reach several metres high. The interaction of corals, algae, and bryozoa is largely responsible for the framework of features known as organic reefs, which abound in tropical marine settings. Some of these reefs have given rise to entire insular land areas many kilometres in diameter. The largest example is the Great Barrier Reef of Australia, which covers an area of about 207,000 square kilometres. Though nearly submerged today, it was an island during the Pleistocene glaciation.

Micro topographic features

With the possible exception of the Great Barrier Reef, all major biogenic landforms produced in recent times are attributable to the activities of humankind. The construction of modern superhighways involves some of the most extensive terrain changes on Earth, having in some cases resulted in the removal of mountains or at least large portions thereof. Many human effects are not necessarily tied to particular construction projects. On a subtler level, the removal of fluids from the ground, principally water and petroleum, have dropped water tables and reduced pore pressure so greatly that extensive areas have experienced subsidence, collapse, and shrinkage. Terrain changes due to groundwater removal are extremely severe in such regions as the southwestern United States or the area near Mexico City. To the foregoing human effects on topography must be added the bomb craters left by war that are ever so slowly being obliterated from Europe and Asia, and the erosional gullying of terrain where uncontrolled deforestation has been allowed. Finally, there are the engineering modifications of waterways and coasts practiced nowhere more intensively than in the United States and Europe. River flow patterns have been drastically altered, usually by channel straightening, and the construction of large dams has converted entire valleys, gorges, and canyons into lakes. In fact, dams are among the largest biogenic landforms produced. (H.F.G.)

Impact of human activities

BIBLIOGRAPHY

Landform evolution and theoretical views: The seminal works of WILLIAM MORRIS DAVIS, especially his 1899 essay "The Geographical Cycle" and his 1905 essay "The Geographical Cycle in an Arid Climate," both reprinted in *Geographical Essays* (1909, reprinted 1954), paved the way for WALTHER PENCK, *Morphological Analysis of Land Forms: A Contribution to Physical Geology* (1953, reprinted 1972; originally published in German, 1924); and for LESTER C. KING, "Canons of Landscape Evolution," *Bulletin of the Geological Society of America,* 64:721–752 (1953). Davis' thinking continued to dominate geomorphic theory in such textbooks as A.K. LOBECK, *Geomorphology: An Introduction to the Study of Landscapes* (1939); and WILLIAM D. THORNBURY, *Principles of Geomorphology,* 2nd ed. (1968). The history of geomorphic theory up to the time of Davis is told in RICHARD J. CHORLEY, ANTONY J. DUNN, and ROBERT P. BECKINSALE, *The History of the Study of Landforms,* 2 vol. (1964–73). CUCHLAINE A.M. KING (ed.), *Landforms and Geomorphology: Concepts and History* (1976), contains a historical collection of key papers in the development of geomorphic ideas from 1802 to 1972. Introductory essays on the many aspects of the field may be found in ALISTAIR PITTY (ed.), *Geomorphology: Themes and Trends* (1985).

The first comprehensive attempt to synthesize geomorphic thinking on a systems level that incorporates modern tectonic, climatic, and process aspects is H.F. GARNER, *The Origin of Landscapes: A Synthesis of Geomorphology* (1974). An analysis of these and other geomorphic theories to date appeared in WILLIAM N. MELHORN and RONALD C. FLEMAL (eds.), *Theories of Landform Development* (1975, reissued 1980). More restricted aspects of geomorphology are dealt with in LUNA B. LEOPOLD, M. GORDON WOLMAN, and JOHN P. MILLER, *Fluvial Processes in Geomorphology* (1964); G.H. DURY (ed.), *Essays in Geomorphology* (1966); J. TRICART and A. CAILLEUX, *Introduction to Climatic Geomorphology* (1972; originally published in French, 1965); ROBERT V. RUHE, *Geomorphology: Geomorphic Processes and Surficial Geology* (1975); C.R. TWIDALE, *Analysis*

of Landforms (1975, reprinted 1976); R.J. RICE, *Fundamentals of Geomorphology* (1977); DALE F. RITTER, *Process Geomorphology,* 2nd ed. (1986); and RITA GARDNER and HELEN SCOGING (eds.), *Mega-Geomorphology* (1983).

(H.F.G.)

Tectonic landforms: (*Tectonic processes*): An excellent introduction to geology, somewhat dated but very well illustrated, is ARTHUR HOLMES, *Principles of Physical Geology,* 2nd rev. ed. (1965), with a particularly good treatment of rift valleys. WILLIAM J. PERRY, DIETRICH H. RODER, and DAVID R. LAGESON (comps.), *North American Thrust-Faulted Terranes* (1984), is a collection of technical papers describing segments of folded and thrusted mountain belts in North America and the mechanics of such deformation. Introductory articles on volcanism at hot spots and island arcs include K. BURKE and T. WILSON, "Hot Spots on the Earth's Surface," *Scientific American,* 235(2):46–57 (August 1976); and BRUCE D. MARSH, "Island-Arc Volcanism," *American Scientist,* 67(2):161–172 (March-April 1979). A discussion of the forces that support mountain ranges and how some ranges are constructed can be found in PETER MOLNAR, "The Structure of Mountain Ranges," *Scientific American,* 255(1):70–79 (July 1986).

(*Mountain systems*): Detailed introductions to the European Alps are E.R. OXBURGH, *The Geology of the Eastern Alps* (1968), concentrating on Austria; and R. TRÜMPY, *An Outline of the Geology of Switzerland,* vol. 1 of *Geology of Switzerland: A Guide-Book,* ed. by the SCHWEIZERISCHE GEOLOGISCHE KOMMISSION (1980). Introductory articles on other mountain belts of the world are found in *Scientific American,* including the following: DON L. ANDERSON, "The San Andreas Fault," 225(5):52–68 (November 1971); PETER MOLNAR and PAUL TAPPONNIER, "The Collision Between India and Eurasia," 236(4):30–41 (April 1977), describing the evolution of mountain belts in eastern Asia; and DAVID L. JONES *et al.,* "The Growth of Western North America," 247(5):70–84 (November 1982), describing the accretion of exotic terrains to that area. Two useful articles in *Geological Society of America Bulletin* are TANYA ATWATER, "Implications of Plate Tectonics for the Cenozoic Tectonic Evolution of Western North America," 81(12):3513–35 (December 1970), a classic article that changed the way geologists view that region; and JOHN F. DEWAY *et al.,* "Plate Tectonics and the Evolution of the Alpine System," 84(10)3137–80 (October 1973), a summary of motions of lithospheric plates and mountain building in the Mediterranean area. See also PETER MOLNAR, "The Geologic History and Structure of the Himalaya," *American Scientist,* 74(2):144–154 (March-April 1986), describing how the structure of the Himalayas allows the chain to achieve its great height.

(*Rift valleys*): B.H. BAKER, P.A. MOHR, and L.A.J. WILLIAMS, *Geology of the Eastern Rift System of Africa* (1972), provides a summary of the eastern branch of the East African Rift System. More specific treatment is found in B.H. BAKER and J. WOHLENBERG, "Structure and Evolution of the Kenya Rift Valley," *Nature,* 229(5286):538–542 (Feb. 19, 1971).

(P.H.M.)

Structural landforms: Landforms resulting from erosion and deposition are analyzed in RICHARD J. CHORLEY, STANLEY A. SCHUMM, and DAVID E. SUGDEN, *Geomorphology* (1984); and DALE F. RITTER, *Process Geomorphology,* 2nd ed. (1986).

(*Stream valleys and canyons*): Descriptions can be found in geomorphology textbooks, including M.J. SELBY, *Earth's Changing Surface: An Introduction to Geomorphology* (1985); and ARTHUR L. BLOOM, *Geomorphology: A Systematic Analysis of Late Cenozoic Landforms* (1978). The relevant fluvial phenomena are treated in DAVID KNIGHTON, *Fluvial Forms and Processes* (1984); and the relevant hillslope phenomena in M.J. SELBY, *Hillslope Materials and Processes* (1982). More specialized topics include the following: VICTOR R. BAKER, *The Channels of Mars* (1982); THEODORE OBERLANDER, *The Zagros Streams: A New Interpretation of Transverse Drainage* (1965); JULIUS BÜDEL, *Climatic Geomorphology* (1982; originally published in German, 1977); and GEORGE F. ADAMS (ed.), *Planation Surfaces: Peneplains, Pediplains, and Etchplains* (1975).

(*Playas, pans, and saline flats*): A useful collection of scientific papers is JAMES T. NEAL (ed.), *Playas and Dried Lakes: Occurrence and Development* (1975). The playas of Death Valley, California, are described by CHARLES B. HUNT, *Death Valley: Geology, Ecology, and Archaeology* (1975).

(V.R.B.)

(*Sand dunes*): Descriptions and geographic distribution of forms produced by wind deposition are provided in a still-useful classic text, R.A. BAGNOLD, *The Physics of Blown Sand and Desert Dunes* (1941, reprinted 1984). More information is given in K.W. GLENNIE, *Desert Sedimentary Environments* (1970); RONALD U. COOKE and ANDREW WARREN, *Geomorphology in Deserts* (1973); EDWIN D. MCKEE, CAROL S. BREED, and STEVEN G. FRYBERGER, "Desert Sand Seas," ch. 2 in *Skylab Explores the Earth* (1977), pp. 5–48, NASA document sp 380; CAROL S. BREED, MAURICE J. GROLIER, and JOHN F. MCCAULEY, "Morphology and Distribution of Common Sand Dunes on Mars: Comparison with the Earth," *Journal of Geophysical Research,* 84(B14):8183–8204 (Dec. 30, 1979); EDWIN D. MCKEE (ed.), *A Study of Global Sand Seas* (1979); CAROL S. BREED *et al.,* "Eolian (Wind-Formed) Landforms," in TERAH L. SMILEY *et al.* (eds.), *Landscapes of Arizona: The Geological Story* (1984), pp. 359–413; and RONALD GREELEY and JAMES D. IVERSEN, *Wind as a Geological Process: On Earth, Mars, Venus, and Titan* (1985).

(W.J.Br./C.S.Br.)

(*Glacial and periglacial landforms*): The classic text on glacial geology is RICHARD FOSTER FLINT, *Glacial and Quaternary Geology* (1971), encyclopaedic coverage including an extensive bibliography. Recent hypotheses and observations on glacial erosion and deposition are included in DAVID DREWRY, *Glacial Geologic Processes* (1986), even though the coverage of glacial landforms is not complete. DAVID E. SUGDEN and BRIAN S. JOHN, *Glaciers and Landscape: A Geomorphological Approach* (1976, reprinted 1984), is an excellent detailed introduction to glacial landforms and the processes that shaped them. More theoretical emphasis can be found in CLIFFORD EMBLETON and CUCHLAINE A.M. KING, *Glacial Geomorphology,* 2nd ed. (1975), and *Periglacial Geomorphology,* 2nd ed. (1975). A.L. WASHBURN, *Geocryology: A Survey of Periglacial Processes and Environments* (1979), contains numerous explanatory photographs and diagrams. A collection of articles is found in CUCHLAINE A.M. KING (ed.), *Periglacial Processes* (1976).

(E.B.E./Gu.S.)

(*Caves and karst topography*): Two introductory texts are ALFRED BÖGLI, *Karst Hydrology and Physical Speleology* (1980; originally published in German, 1978), emphasizing caves; and J.N. JENNINGS, *Karst Geomorphology,* 2nd rev. ed. (1985), covering both caves and surface landforms—a recommended introduction to karst. Discussion of cave geology, hydrology, mineralogy, and biology can be found in T.D. FORD and C.H.D. CULLINGFORD (eds.), *The Science of Speleology* (1976), with a good chapter on volcanic caves. CAROL A. HILL and PAOLO FORTI, *Cave Minerals of the World* (1986), is a systematic description of minerals and speleothems. PAUL COURBON and CLAUDE CHABERT, *Atlas des grandes cavités mondiales* (1986), provides a definitive world list of long and deep caves, with maps and descriptive texts. Country-by-country review chapters on karst geology and surface landforms are contained in M. HERAK and V.T. STRINGFIELD (eds.), *Karst: Important Karst Regions of the Northern Hemisphere* (1972), concentrating mostly on Europe, the U.S.S.R., and the United States.

(W.B.Wh.)

(*Coastal processes*): An introduction to coastal geomorphology is provided by ERIC C.F. BIRD, *Coasts* (1984). Other useful texts include FRANCIS P. SHEPARD and HAROLD R. WANLESS, *Our Changing Coastlines* (1971); PAUL D. KOMAR, *Beach Processes and Sedimentation* (1976); J.L. DAVIES, *Geographical Variation in Coastal Development,* 2nd ed. (1980); and RICHARD A. DAVIS, JR., *Coastal Sedimentary Environments,* 2nd rev. and expanded ed. (1985). ERIC C.F. BIRD and MAURICE L. SCHWARTZ (eds.), *The World's Coastline* (1985), is a comprehensive round-the-world treatment of coastal features.

(R.A.D.)

(*Impact craters*): Two general books on the subject are RONALD GREELEY, *Planetary Landscapes* (1985); and BRUCE MURRAY, MICHAEL C. MALIN, and RONALD GREELEY, *Earthlike Planets: Surfaces of Mercury, Venus, Earth, Moon, Mars* (1981). Collected papers from scientific meetings include BEVAN N. FRENCH and NICHOLAS M. SHORT (eds.), *Shock Metamorphism of Natural Materials* (1968); and LEON T. SILVER and PETER H. SCHULTZ (eds.), *Geological Implications of Impacts of Large Asteroids and Comets on the Earth* (1982), in which see especially RICHARD A.F. GRIEVE, "The Record of Impact on Earth: Implications for a Major Cretaceous/Tertiary Impact Event," pp. 25–37.

(C.R.S.)

Copernicus

Nicolaus Copernicus (Mikołaj Kopernik) was a Polish astronomer who proposed that the planets have the Sun as the fixed point to which their motions are to be referred and that the Earth is a planet which orbits around the Sun. This representation of the heavens—usually called the heliocentric, or "Sun-centred," system—had important consequences for later thinkers of the scientific revolution, including such major figures as Galileo, Kepler, Descartes, and Newton. Copernicus probably hit upon his theory sometime between 1508 and 1514, although the book that contains the final version of his theory, *De revolutionibus orbium coelestium libri vi* ("Six Books Concerning the Revolutions of the Heavenly Orbs"), was not printed until 1543, the year of his death.

By courtesy of the Museum of Jagiellonian University, Kraków, Poland

Copernicus, 17th-century copy of a 16th-century self-portrait. In the Museum of Jagiellonian University, Kraków, Poland.

Early life and education. Certain facts about Copernicus's early life are well established, although a biography written by his ardent disciple Georg Joachim Rheticus (1514–74) is unfortunately lost. According to a later horoscope, Nicolaus Copernicus was born on February 19, 1473, in Toruń, a city in north-central Poland on the Vistula River south of the major Baltic seaport of Gdańsk. His father, Nicolaus, was a well-to-do merchant, and his mother, Barbara Watzenrode, also came from a leading merchant family. Nicolaus was the youngest of four children. After his father's death, sometime between 1483 and 1485, his mother's brother Lucas Watzenrode (1447–1512) took his nephew under his protection. Watzenrode, soon to be bishop of the chapter of Varmia (Warmia), saw to young Nicolaus's education and his future career.

Education in astronomy and astrology

Between 1491 and about 1494 Copernicus studied liberal arts—including astronomy and astrology—at the University of Cracow (Kraków). Like many students of his time, however, he left before completing his degree. He resumed his studies in Italy at the University of Bologna, where his uncle had obtained a doctorate in canon law. The Bologna period (1496–1500) was short but significant. For a time Copernicus lived in the same house as the principal astronomer at the university, Domenico Maria de Novara (Domenicus Maria Novaria Ferrariensis; 1454–1504). Novara had the responsibility of issuing annual astrological prognostications for the city, forecasts that included all social groups but gave special attention to the fate of the Italian princes and their enemies. Copernicus was "assistant and witness" to some of Novara's observations, and his involvement with the production of the annual forecasts means that he was intimately familiar with the practice of astrology. Novara also probably introduced Copernicus to two important books that framed his future problematic in the study of the heavens: *Epitoma in Almagestum Ptolemaei* ("Epitome of Ptolemy's Almagest") by Johann Müller (also known as Regiomontanus, 1436–76) and *Disputationes adversus astrologiam divinatricem* ("Disputations against Divinatory Astrology") by Giovanni Pico della Mirandola (1463–94). The first provided a summary of Ptolemy's astronomy, with Regiomontanus's corrections and expansions of certain important planetary models that might have been suggestive to Copernicus of the heliocentric hypothesis. Pico's *Disputationes* offered a devastating skeptical attack on the foundations of astrology that reverberated into the 17th century. Among Pico's criticisms was the charge that, because astronomers disagreed about the order of the planets, astrologers could not be certain about the strengths of the powers issuing from the planets.

Only 27 recorded observations are known for Copernicus's entire life (he undoubtedly made more than that), most of them concerning eclipses, alignments, and conjunctions of planets and stars. The first such known observation occurred on March 9, 1497, at Bologna. In 1500 Copernicus spoke before an interested audience in Rome on mathematical subjects, but the exact content of his lectures is unknown. In 1501 he stayed briefly in Frauenburg (now Frombork, Pol.) but soon returned to Italy to pursue medical studies at the University of Padua. At this time the stars were thought to influence the body's dispositions, so that Copernicus's astrological experience at Bologna was better training for medicine than one might imagine today. In May 1503 he finally received a doctorate—like his uncle, in canon law—but from an Italian university where he had not studied: the University of Ferrara. When he returned to Poland, Bishop Watzenrode arranged a sinecure for him: an in absentia teaching post, or scholastry, at Wrocław. Copernicus's actual duties as a church canon at the bishopric palace, however, were largely administrative and medical. His astronomical work took place in his spare time. He also prepared a Latin translation of the aphorisms of an obscure 7th-century Byzantine historian and poet, Theophylactus Simocattes, which was published in Cracow in 1509 and dedicated to his uncle. It was during the last years of Watzenrode's life that Copernicus evidently came up with the idea on which his fame was to rest.

Copernicus's astronomical work. The principal historical background to Copernicus's achievement was the contested state of planetary theory in the late 15th century and also Pico's attack on astrology. In Copernicus's period, astrology and astronomy were considered subdivisions of a common "science of the stars," whose main aim was to describe the arrangement of the heavens and to provide the theoretical tools and tables of motions needed to construct horoscopes and annual prognostications. The terms "astrologer," "astronomer," and "mathematician" were virtually interchangeable; they generally denoted anyone who studied the heavens using mathematical techniques.

Pico claimed that astrology ought to be condemned because its practitioners were in disagreement about everything, from the divisions of the zodiac to the order of the planets. A second long-standing disagreement, not mentioned by Pico, concerned the status of the planetary models. From antiquity, astronomical modeling was governed by the premise that the planets move with uniform angular motion at a constant distance from their centres of motion. Two types of models derived from this premise. The first, represented by Aristotle, held that the planets are car-

The classical models of the heavens

ried around the centre of the universe embedded in unchangeable, material, invisible spheres. As a predictive model, this account was of limited value. Among other things, it could not account for variations in the apparent brightness of the planets, since the distances from the centre were always the same, and it could not account for retrograde motion, when the planets seemed to stop and even move backward and forward in a loop. A second tradition, deriving from Claudius Ptolemy, solved these problems by postulating three mechanisms: uniformly revolving, off-centre circles called eccentrics; epicycles, little circles whose centres moved uniformly on the circumference of circles of larger radius (deferents); and equants, imaginary points in space where uniform, circular speed would be observed. The equant, however, broke with the main assumption of ancient astronomy because it separated the condition of uniform motion from that of constant distance from the centre. According to this theory, a planet viewed from the centre of its orbit would appear to move sometimes faster, sometimes slower, and seen from Earth it would also appear to move nonuniformly. Only from the equant would the planet appear to move uniformly.

Over the centuries Persian astronomers had devised a model that would produce equalized motion without referring to an equant point, and Copernicus learned to do this "trick." But this insight was only the starting point for his attempt to bring all the models together into a coordinated arrangement. Copernicus was disturbed by Pico's charge that astronomers could not agree on the actual order of the planets. The difficulty focused on the locations of Venus and Mercury. There was general agreement that the Moon and Sun encircled the motionless Earth and that Mars, Jupiter, and Saturn were situated beyond the Sun in that order. However, Ptolemy placed Venus closest to the Sun and Mercury to the Moon, while others claimed that Mercury and Venus were beyond the Sun.

The Copernican model

In a manuscript usually called the *Commentariolus* ("Little Commentary"), Copernicus postulated that, if the Sun is assumed to be at rest and if the Earth is assumed to be in motion, then the remaining planets will fall into an orderly relationship whereby their sidereal periods increase from the Sun as follows: Mercury (88 days), Venus (225 days), Earth (1 year), Mars (1.9 years), Jupiter (12 years), and Saturn (30 years). This theory did resolve the disagreement about the ordering of the planets but, in turn, raised new problems. To accept the theory's premises, one had to abandon much of Aristotelian natural philosophy and develop a new explanation for why heavy bodies fall to a moving Earth. It was also necessary to explain how a transient body like the Earth, filled with meteorological phenomena, pestilence, and wars, could be part of a perfect and imperishable heaven. In addition, Copernicus knew he was working with many observations inherited from antiquity whose trustworthiness he could not verify.

Any of these considerations alone could account for Copernicus's delay in publishing his work. When a description of the main elements of the heliocentric hypothesis was first published, in the *Narratio prima* (1540 and 1541, "First Narration"), it was not under Copernicus's own name but under that of the 25-year-old Georg Rheticus. Rheticus, a Lutheran from the University of Wittenberg, Germany, stayed with Copernicus at Frauenburg for about two and a half years, between 1539 and 1542. The *Narratio prima* was in effect something of a "trial balloon" for the main work. It provided a summary of the theoretical principles contained in the manuscript of *De revolutionibus,* emphasized their value for computing new planetary tables, and presented Copernicus as following admiringly in the footsteps of Ptolemy even as he broke fundamentally with his ancient predecessor.

Both Rheticus and Copernicus knew that they could not definitively rule out all possible alternatives to the heliocentric theory. But they could underline what Copernicus's theory provided that others could not: a singular method for ordering the planets and for calculating the relative distances of the planets from the Sun. In the preface to *De revolutionibus,* Copernicus used an image from Horace's *Ars poetica* ("Art of Poetry"). The theories of his predecessors, he wrote, were like a human figure in which the arms, legs, and head were put together in the form of a disorderly monster. His own representation of the universe, in contrast, was an orderly whole in which a displacement of any part would result in a disruption of the whole. In effect, a new criterion of scientific adequacy was advanced together with the new theory of the universe.

Publication of *De revolutionibus*. The presentation of Copernicus's theory in its final form is inseparable from the conflicted history of its publication. When Rheticus left Frauenburg to return to his teaching duties at Wittenberg, he took the manuscript with him in order to arrange for its publication at Nürnberg, the leading centre of printing in Germany. He chose the top printer in the city, Johann Petreius, who had published a number of ancient and modern astrological works during the 1530s. Unfortunately, Rheticus was unable to remain and supervise the printing. He turned the manuscript over to Andreas Osiander (1498–1552), a theologian experienced in shepherding mathematical books through production as well as a leading political figure in the city and an ardent follower of Luther (although he was eventually expelled from the Lutheran church). Osiander made changes without the permission of either Rheticus or Copernicus. First, the title of the work was changed from the manuscript's "On the Revolutions of the Orbs of the World" to "Six Books Concerning the Revolutions of the Heavenly Orbs"—a change that appeared to mitigate the book's claim to describe the real universe. In addition, Osiander added an unsigned "letter to the reader" directly after the title page, which maintained that the hypotheses contained within made no pretense to truth and that, in any case, astronomy was incapable of finding the causes of heavenly phenomena. Rheticus's rage was so great that he crossed out the letter with a great red X in the copies sent to him. However, no public revelation of Osiander's role was made until Kepler revealed it in his *Astronomia Nova* (*New Astronomy*) in 1609.

Osiander's changes

Ironically, Osiander's "letter" made it possible for the book to be read as a new method of calculation, rather than a work of natural philosophy, and in so doing it may even have aided in the book's initially positive reception. It was not until Kepler that Copernicus's cluster of predictive mechanisms would be fully transformed into a new philosophy about the fundamental structure of the universe.

Legend has it that a copy of *De revolutionibus* was placed in Copernicus's hands in Frauenburg a few days after he lost consciousness from a stroke. On May 24, 1543, he awoke long enough to realize that he was holding his great book and then expired, publishing as he perished. The legend has some credibility, although it also has the beatific air of a saint's life.

BIBLIOGRAPHY. Copernicus's complete works are collected in English translation in *On the Revolutions,* ed. and trans. by EDWARD ROSEN (1978, reissued 1992); and *Minor Works,* ed. and trans. by EDWARD ROSEN and ERNA HILFSTEIN (1985, reissued 1992). Biographies include ANGUS ARMITAGE, *Copernicus: Founder of Modern Astronomy* (1938, reissued 1990); and EDWARD ROSEN, *Copernicus and the Scientific Revolution* (1984), both for the general reader; and the more scholarly biography in N.M. SWERDLOW and O. NEUGEBAUER, *Mathematical Astronomy in Copernicus's De Revolutionibus,* vol. 1 (1984). A general overview of Copernicus's ideas and their impact is presented in THOMAS S. KUHN, *The Copernican Revolution: Planetary Astronomy in the Development of Western Thought* (1957, reissued 1985). ROBERT S. WESTMAN, "Two Cultures or One? A Second Look at Kuhn's The Copernican Revolution," *Isis,* 85:79–115 (March 1994), provides a critical reevaluation with a more recent bibliography. The series *Studia Copernicana* (1970–), which offers a rich collection of scholarly studies on aspects of Copernicus's life, work, and later reception; and ROBERT S. WESTMAN (ed.), *The Copernican Achievement* (1975), are recommended for advanced study. OWEN GINGERICH, *The Great Copernicus Chase and Other Adventures in Astronomical History* (1992), and *The Eye of Heaven: Ptolemy, Copernicus, Kepler* (1993), are useful for scholarly and general readers. (R.S.We.)

The Cosmos

If one looks up on a clear night, one sees that the sky is full of stars. During the summer months in the Northern Hemisphere, a faint band of light stretches from horizon to horizon, a swath of pale white cutting across a background of deepest black. For the early Egyptians, this was the heavenly Nile, flowing through the land of the dead ruled by Osiris. The ancient Greeks likened it to a river of milk. Astronomers now know that the band is actually composed of countless stars in a flattened disk seen edge on. The stars are so close to one another along the line of sight that the unaided eye has difficulty discerning the individual members. Through a large telescope, astronomers find myriads of like systems sprinkled throughout the depths of space. They call such vast collections of stars galaxies, after the Greek word for milk, and call the local galaxy to which the Sun belongs the Milky Way Galaxy or simply the Galaxy.

Every visible star is a sun in its own right. Ever since this realization first dawned in the collective mind of humanity, it has been speculated that many stars other than the Sun also have planetary systems encircling them. The related issue of the origin of the solar system, too, has always had special fascination for speculative thinkers, and the quest to understand it on a firm scientific basis has continued into the present day.

Some stars are intrinsically brighter than the Sun; others, fainter. Much less light is received from the stars than from the Sun because the stars are all much farther away. Indeed, they appear densely packed in the Milky Way only because there are so many of them. The actual separations of the stars are enormous, so large that it is conventional to measure their distances in units of how far light can travel in a given amount of time. The speed of light (in a vacuum) equals 3×10^{10} cm/sec (centimetres per second); at such a speed, it is possible to circle the Earth seven times in a single second. Thus in terrestrial terms the Sun, which lies 500 light-seconds from the Earth, is very far away; however, even the next closest star, Proxima Centauri, at a distance of 4.3 light-years (4.1×10^{18} cm), is 270,000 times farther yet. The stars that lie on the opposite side of the Milky Way from the Sun have distances that are on the order of 100,000 light-years, which is the typical diameter of a large spiral galaxy.

If the kingdom of the stars seems vast, the realm of the galaxies is larger still. The nearest galaxies to the Milky Way system are the Large and Small Magellanic Clouds, two irregular satellites of the Galaxy visible to the naked eye in the Southern Hemisphere. The Magellanic Clouds are relatively small (containing roughly 10^9 stars) compared to the Galaxy (with some 10^{11} stars), and they lie at a distance of about 200,000 light-years. The nearest large galaxy comparable to the Galaxy is the Andromeda galaxy (also called M31 because it was the 31st entry in a catalog of astronomical objects compiled by the French astronomer Charles Messier in 1781), and it lies at a distance of about 2,000,000 light-years. The Magellanic Clouds, the Andromeda galaxy, and the Milky Way system all are part of an aggregation of two dozen or so neighbouring galaxies known as the Local Group. The Galaxy and M31 are the largest members of this group.

The Galaxy and M31 are both spiral galaxies, and they are among the brighter and more massive of all spiral galaxies. The most luminous and brightest galaxies, however, are not spirals but rather supergiant ellipticals (also called cD galaxies by astronomers for historical reasons that are not particularly illuminating). Elliptical galaxies have roundish shapes rather than the flattened distributions that characterize spiral galaxies, and they tend to occur in rich clusters (those containing thousands of members) rather than in the loose groups favoured by spirals.

The brightest member galaxies of rich clusters have been detected at distances exceeding several thousand million light-years from the Earth. The branch of learning that deals with phenomena at the scale of many millions of light-years is called cosmology—a term derived from combining two Greek words, *kosmos,* meaning "order," "harmony," and "the world," and *logos,* signifying "word" or "discourse." Cosmology is, in effect, the study of the universe at large. A dramatic new feature, not present on small scales, emerges when the universe is viewed in the large—namely, the cosmological expansion. On cosmological scales, galaxies (or, at least, clusters of galaxies) appear to be racing away from one another with the apparent velocity of recession being linearly proportional to the distance of the object. This relation is known as the Hubble law (after its discoverer, the American astronomer Edwin Powell Hubble). Interpreted in the simplest fashion, the Hubble law implies that roughly 10^{10} years ago, all of the matter in the universe was closely packed together in an incredibly dense state and that everything then exploded in a "big bang," the signature of the explosion being written eventually in the galaxies of stars that formed out of the expanding debris of matter. Strong scientific support for this interpretation of a big bang origin of the universe comes from the detection by radio telescopes of a steady and uniform background of microwave radiation. The cosmic microwave background is believed to be a ghostly remnant of the fierce light of the primeval fireball reduced by cosmic expansion to a shadow of its former splendour but still pervading every corner of the known universe.

The simple (and most common) interpretation of the Hubble law as a recession of the galaxies over time through space, however, contains a misleading notion. In a sense, as will be made more precise later in the article, the expansion of the universe represents not so much a fundamental motion of galaxies within a framework of absolute time and absolute space, but an expansion of time and space themselves. On cosmological scales, the use of light-travel times to measure distances assumes a special significance because the lengths become so vast that even light, traveling at the fastest speed attainable by any physical entity, takes a significant fraction of the age of the universe, roughly 10^{10} years, to travel from an object to an observer. Thus, when astronomers measure objects at cosmological distances from the Local Group, they are seeing the objects as they existed during a time when the universe was much younger than it is today. Under these circumstances, Albert Einstein taught in his theory of general relativity that the gravitational field of everything in the universe so warps space and time as to require a very careful reevaluation of quantities whose seemingly elementary natures are normally taken for granted.

The observed expansion of the universe immediately raises the spectre that the universe is evolving, that it had a beginning and will have an end. The steady state alternative, postulated by a British school of cosmologists in 1948, is no longer considered viable by most astronomers. Yet, the notion that the Cosmos had a beginning, while common in many theologies, raises deep and puzzling questions for science, for it implies a creation event—a creation not only of all the mass-energy that now exists in the universe but also perhaps of space-time itself.

The issue of how the universe will end seems, at first sight, more amenable to conventional analysis. Because the universe is currently expanding, one may ask whether this expansion will continue into the indefinite future or whether after the passage of some finite time, the expansion will be reversed by the gravitational attraction of all of the matter for itself. The procedure for answering this question seems straightforward: either measure directly the rate of deceleration in the expansion of the galaxies to extrapolate whether they will eventually come to a halt,

or measure the total amount of matter in the universe to see if there is enough to supply the gravitation needed to make the universe bound. Unfortunately, astronomers' assaults on both fronts have been stymied by two unforeseen circumstances. First, it is now conceded that earlier attempts to measure the deceleration rate have been affected by evolutionary effects of unknown magnitude in the observed galaxies that invalidate the simple interpretations. Second, it is recognized that within the Cosmos there may be an unknown amount of "hidden mass," which cannot be seen by conventional astronomical techniques but which contributes substantially to the gravitation of the universe.

The hope is that, somehow, quantum physics will ultimately supply theoretical answers (which can then be tested observationally and experimentally) to each of these difficulties. The ongoing effort in particle physics to find a unified basis for all the elementary forces of nature has yielded promising new ways to think about the most fundamental of all questions regarding astronomical origins; it has offered a tentative prediction concerning the deceleration rate of the universe; and it has offered a plethora of candidates for the hidden mass of the universe.

This article traces the development of modern conceptions of the Cosmos and summarizes the prevailing theories of its origin and evolution. Humanity has traveled a long road since self-centred societies imagined the creation of the Earth, the Sun, and the Moon as the main act, with the formation of the rest of the universe as almost an afterthought. Today it is known that the Earth is only a small ball of rock in a Cosmos of unimaginable vastness and that the birth of the solar system was probably only one event among many that occurred against the backdrop of an already mature universe. Yet, as humbling as the lesson has been, it has also unveiled a remarkable fact, one that endows the minutest particle in this universe with a rich and noble heritage. Events hypothesized to have occurred in the first few minutes of the creation of the universe turn out to have had profound influence on the birth, life, and death of galaxies, stars, and planets. Indeed, there is a direct, though tortuous, lineage from the forging of the matter of the universe in a primal furnace of incredible heat and light to the gathering on Earth of atoms versatile enough to serve as a chemical basis of life. The intrinsic harmony of the resultant worldview has great philosophical and aesthetic appeal and perhaps explains the resurgence of public interest in this subject.

For detailed information on the structure and evolution of the major components of the Cosmos, see GALAXIES; STARS AND STAR CLUSTERS; NEBULA; and SOLAR SYSTEM, THE. (See also the *Propædia,* sections 132 and 133, and the *Index.*) The present article considers only aspects of these topics that satisfy one of three criteria: (1) they bear on the general issue of astronomical origins; (2) they are important to an integrated picture of how the universe evolved; or (3) they play a big role in forming humanity's growing vision of the miraculous unity that is the Cosmos.

The article is divided into the following sections:

History of humanity's perception of the universe

EARLIEST CONCEPTIONS

All scientific thinking on the nature of the Cosmos can be traced to the distinctive geometric patterns formed by the stars in the night sky. Even prehistoric people must have noticed that, apart from a daily rotation (which is now understood to arise from the spin of the Earth), the stars did not seem to move with respect to one another: the stars appear "fixed." Early nomads found that knowledge of the constellations could guide their travels, and they developed stories to help them remember the relative positions of the stars in the night sky. These stories became the mythical tales that are part of most cultures.

When nomads turned to farming, an intimate knowledge of the constellations served a new function—an aid in timekeeping, in particular for keeping track of the seasons. People had noticed very early that certain celestial objects did not remain stationary relative to the "fixed" stars; instead, during the course of a year, they moved forward and backward in a narrow strip of the sky that contained 12 constellations constituting the signs of the zodiac. Seven such wanderers were known to the ancients:

the Sun, Moon, Mercury, Venus, Mars, Jupiter, and Saturn. Foremost among the wanderers was the Sun: day and night came with its rising and setting, and its motion through the zodiac signaled the season to plant and the season to reap. Next in importance was the Moon: its position correlated with the tides and its shape changed intriguingly over the course of a month. The Sun and Moon had the power of gods; why not then the other wanderers? Thus probably arose the astrological belief that the positions of the planets (from the Greek word *planetes*, "wanderers") in the zodiac could influence worldly events and even cause the rise and fall of kings. In homage to this belief, Babylonian priests devised the week of seven days, whose names even in various modern languages (for example, English, French, or Norwegian) can still easily be traced to their origins in the seven planet-gods.

ASTRONOMICAL THEORIES OF THE ANCIENT GREEKS

The apex in the description of planetary motions during classical antiquity was reached with the Greeks, who were of course superb geometers. Like their predecessors, Greek astronomers adopted the natural picture, from the point of view of an observer on Earth, that the Earth lay motionless at the centre of a rigidly rotating celestial sphere (to which the stars were "fixed"), and that the complex to-and-fro wanderings of the planets in the zodiac were to be described against this unchanging backdrop. They developed an epicyclic model that would reproduce the observed planetary motions with quite astonishing accuracy. The model invoked small circles on top of large circles, all rotating at individual uniform speeds, and it culminated about AD 140 with the work of Ptolemy, who introduced the ingenious artifact of displaced centres for the circles to improve the empirical fit. Although the model was purely kinematic and did not attempt to address the dynamical reasons for why the motions were as they were, it laid the groundwork for the paradigm that nature is not capricious but possesses a regularity and precision that can be discovered from experience and used to predict future events.

Ptolemy and the epicyclic model

The application of the methods of Euclidean geometry to planetary astronomy by the Greeks led to other schools of thought as well. Pythagoras (*c.* 570–? BC), for example, argued that the world could be understood on rational principles ("all things are numbers"); that it was made of four elements—earth, water, air, and fire; that the Earth was a sphere; and that the Moon shone by reflected light. In the 4th century BC Heracleides, a follower of Pythagoras, taught that the spherical Earth rotated freely in space and that Mercury and Venus revolved about the Sun. From the different lengths of shadows cast in Syene and Alexandria at noon on the first day of summer, Eratosthenes (*c.* 276–194 BC) computed the radius of the Earth to an accuracy within 20 percent of the modern value. Starting with the size of the Earth's shadow cast on the Moon during a lunar eclipse, Aristarchus of Samos (*c.* 310–230 BC) calculated the linear size of the Moon relative to the Earth. From its measured angular size, he then obtained the distance to the Moon. He also proposed a clever scheme to measure the size and distance of the Sun. Although flawed, the method did enable him to deduce that the Sun is much larger than the Earth. This deduction led Aristarchus to speculate that the Earth revolves about the Sun rather than the other way around.

The heliocentric hypothesis of Aristarchus

Unfortunately, except for the conception that the Earth is a sphere (inferred from the Earth's shadow on the Moon always being circular during a lunar eclipse), these ideas failed to gain general acceptance. The precise reasons remain unclear, but the growing separation between the empirical and aesthetic branches of learning must have played a major role. The unparalleled numerical accuracy achieved by the theory of epicyclic motions for planetary motions lent great empirical validity to the Ptolemaic system. Henceforth, such computational matters could be left to practical astronomers without the necessity of having to ascertain the physical reality of the model. Instead, absolute truth was to be sought through the Platonic ideal of pure thought. Even the Pythagoreans fell into this trap; the depths to which they eventually sank may be judged from the story that they discovered and then tried to conceal the fact that the square root of 2 is an irrational number (*i.e.*, cannot be expressed as a ratio of two integers).

THE SYSTEM OF ARISTOTLE AND ITS IMPACT ON MEDIEVAL THOUGHT

The systematic application of pure reason to the explanation of natural phenomena reached its extreme development with Aristotle (384–322 BC), whose great system of the world later came to be regarded as the synthesis of all worthwhile knowledge. Aristotle argued that humans could not inhabit a moving and rotating Earth without violating commonsense perceptions. Moreover, in his theory of impetus, all terrestrial motion, presumably including that of the Earth itself, would grind to a halt without the continued application of force. He took for granted the action of friction because he would not allow the seminal idealization of a body moving through a void ("nature abhors a vacuum"). Thus, Aristotle was misled into equating force with velocity rather than, as Sir Isaac Newton was to show much later, with (mass times) acceleration. Celestial objects were exempt from dynamical decay because they moved in a higher stratum whereby a perfect sphere was the natural shape of heavenly bodies and uniform rotation in circles was the natural state of their motion. Indeed, primary motion was derived from the outermost sphere, the seat of the unchangeable stars and of divine power. No further explanation was needed beyond the aesthetic one. In this scheme, the imperfect motion of comets had to be postulated as meteorological phenomena that took place within the imperfect atmosphere of the Earth.

The great merit of Aristotle's system was its internal logic, a grand attempt to unify all branches of human knowledge within the scope of a single self-consistent and comprehensive theory. Its great weakness was that its rigid arguments rested almost entirely on aesthetic grounds; it lacked a mechanism by which empirical knowledge gained from experimentation or observation could be used to test, modify, or reject the fundamental principles underlying the theory. Aristotle's system had the underlying philosophical drive of modern science without its flexible procedure of self-correction that allows the truth to be approached in a series of successive approximations.

With the fall of the Roman Empire in AD 476, much of what was known to the Greeks was lost or forgotten—at least to Western civilizations. (Hindu astronomers still taught that the Earth was a sphere and that it rotated once daily.) The Aristotelian system, however, resonated with the teachings of the Roman Catholic Church during the Middle Ages, especially in the writings of St. Thomas Aquinas in the 13th century, and later, during the period of the Counter-Reformation in the 16th and early 17th century, it ascended to the status of religious dogma. Thus did the notion of an Earth-centred universe become gradually enmeshed in the politics of religion. Also welcome in an age that insisted on a literal interpretation of the Scriptures was Aristotle's view that the living species of the Earth were fixed for all time. What was not accepted was Aristotle's argument on logical grounds that the world was eternal, extending infinitely into the past and the future even though it had finite spatial extent. For the church, there was definitely a creation event, and infinity was reserved for God, not space or time.

THE COPERNICAN REVOLUTION

The Renaissance brought a fresh spirit of inquiry to the arts and sciences. Explorers and travelers brought home the vestiges of classical knowledge that had been preserved in the Muslim world and the East, and in the 15th century Aristarchus' heliocentric hypothesis again came to be debated in certain educated circles. The boldest step was taken by the Polish astronomer Nicolaus Copernicus, who hesitated for so long in publication that he did not see a printed copy of his own work until he lay on his deathbed in 1543. Copernicus recognized more profoundly than anyone else the advantages of a Sun-centred planetary system. By adopting the view that the Earth circled the Sun, he could qualitatively explain the to-and-fro wanderings of the planets much more simply than Ptolemy. For example, at certain times in the motions of the Earth

and Mars about the Sun, the Earth would catch up with Mars's projected motion, and then that planet would appear to go backward through the zodiac. Unfortunately in his Sun-centred system, Copernicus continued to adhere to the established tradition of using uniform circular motion, and if he adopted only one large circle for the orbit of each planet, his calculated planetary positions would in fact be quantitatively poorer in comparison with the observed positions of the planets than tables based on the Ptolemaic system. This defect could be partially corrected by providing additional smaller circles, but then much of the beauty and simplicity of Copernicus' original system would be lost. Moreover, though the Sun was now removed from the list of planets and the Earth added, the Moon still needed to move around the Earth.

It was Galileo who exploited the power of newly invented lenses to build a telescope that would accumulate indirect support for the Copernican viewpoint. Critics had no rational response to Galileo's discovery of the correlation of Venus' phases of illumination with its orbital position relative to the Sun, which required it to circle that body rather than the Earth. Nor could they refute his discovery of the four brightest satellites of Jupiter (the so-called Galilean satellites), which demonstrated that planets could indeed possess moons. They could only refuse to look through the telescope or refuse to see what their own eyes told them.

Galileo also mounted a systematic attack on other accepted teachings of Aristotle by showing, for example, that the Sun was not perfect but had spots. Besieged on all sides by what it perceived as heretical stirrings, the church forced Galileo to recant his support of the heliocentric system in 1633. Confined to house arrest during his last years, Galileo would perform actual experiments and thought experiments (summarized in a treatise) that would refute the core of Aristotelian dynamics. Most notably, he formulated the concept that would eventually lead (in the hands of René Descartes) to the so-called first law of mechanics—namely, that a body in motion, freed from friction and from all other forces, would move, not in a circle, but in a straight line at uniform speed. The frame of reference for making such measurements was ultimately the "fixed stars." Galileo also argued that, in the gravitational field of the Earth and in the absence of air drag, bodies of different weights would fall at the same rate. This finding would eventually lead (in the hands of Einstein) to the principle of equivalence, a cornerstone of the theory of general relativity.

Galileo's refutation of Aristotelian dynamics

It was the German astronomer Johannes Kepler, a contemporary of Galileo, who would provide the crucial blow that assured the success of the Copernican revolution. Of all the planets whose orbits Copernicus had tried to explain with a single circle, Mars had the largest departure (the largest eccentricity, in astronomical nomenclature); consequently, Kepler arranged to work with the foremost observational astronomer of his day, Tycho Brahe of Denmark, who had accumulated over many years the most precise positional measurements of this planet. When Kepler finally gained access to the data upon Tycho's death, he painstakingly tried to fit the observations to one curve after another. The work was especially difficult because he had to assume an orbit for the Earth before he could self-consistently subtract the effects of its motion. Finally, after many close calls and rejections, he hit upon a simple, elegant solution—an ellipse with the Sun at one focus. The other planets also fell into place. This triumph was followed by others, notable among which was Kepler's discovery of his so-called three laws of planetary motion. The empirical victory secure, the stage was set for Newton's matchless theoretical campaigns.

Two towering achievements paved the way for Newton's conquest of the dynamical problem of planetary motions: his discoveries of the second law of mechanics and of the law of universal gravitation. The second law of mechanics generalized the work of Galileo and Descartes on terrestrial dynamics, asserting how bodies generally move when they are subjected to external forces. The law of universal gravitation generalized the work of Galileo and the English physicist Robert Hooke on terrestrial gravity, asserting that two massive bodies attract one another with a force directly proportional to the product of their masses and inversely proportional to the square of their separation distance. By pure mathematical deduction, Newton showed that these two general laws (whose empirical basis rested in the laboratory) implied, when applied to the celestial realm, Kepler's three laws of planetary motion. This brilliant coup completed the Copernican program to replace the old worldview with an alternative that was far superior, both in conceptual principle and in practical application. In the same stroke of genius, Newton unified the mechanics of heaven and Earth and initiated the era of modern science.

The contributions of Newton

In formulating his laws, Newton asserted as postulates the notions of absolute space (in the sense of Euclidean geometry) and absolute time (a mathematical quantity that flows in the universe without reference to anything else). A kind of relativity principle did exist ("Galilean relativity") in the freedom to choose different inertial frames of reference—*i.e.*, the form of Newton's laws was unaffected by motion at constant velocity with respect to the "fixed stars." However, Newton's scheme unambiguously sundered space and time as fundamentally separate entities. This step was necessary for progress to be made, and it was such a wonderfully accurate approximation to the truth for describing motions that are slow compared to the speed of light that it withstood all tests for more than two centuries.

In 1705 the English astronomer Edmond Halley used Newton's laws to predict that a certain comet last seen in 1682 would reappear 76 years later. When Halley's comet returned on Christmas night 1758, many years after the deaths of both Newton and Halley, no educated person could ever again seriously doubt the power of mechanistic explanations for natural phenomena. Nor would anyone worry again that the unruly excursions of comets through the solar system would smash the crystalline spheres that earlier thinkers had mentally constructed to carry planets and the other celestial bodies through the heavens. The attention of professional astronomers now turned increasingly toward an understanding of the stars.

In the latter effort, the British astronomer William Herschel and his son John led the assault. The construction of ever more powerful reflecting telescopes allowed them during the late 1700s and early 1800s to measure the angular positions and apparent brightnesses of many faint stars. In an earlier epoch, Galileo had turned his telescope to the Milky Way and saw that it was composed of countless individual stars. Now the Herschels began an ambitious program to gauge quantitatively the distribution of the stars in the sky. On the assumption (first adopted by the Dutch mathematician and scientist Christiaan Huygens) that faintness is a statistical measure of distance, they inferred the enormous average separations of stars. This view received direct confirmation for the nearest stars through parallax measurements of their distances from the Earth. Later, photographs taken over a period of many years also showed that some stars changed locations across the line of sight relative to the background; thus, astronomers learned that stars are not truly fixed, but rather have motions with respect to one another. These real motions—as well as the apparent ones due to parallax, first measured by the German astronomer Friedrich Bessel in 1838—were not detected by the ancients because of the enormous distance scale of the stellar universe.

PERCEPTIONS OF THE 20TH CENTURY

The statistical studies based on these new perceptions continued into the early 20th century. They culminated with the analysis by the Dutch astronomer Jacobus Cornelius Kapteyn who, like William Herschel before him, used number counts of stars to study their distribution in space. It can be shown for stars with an arbitrary but fixed mixture of intrinsic brightnesses that—in the absence of absorption of starlight—the number N of stars with apparent brightness, energy flux f, larger than a specified level f_0, is given by $N = Af_0^{-3/2}$, where A is a constant, if the stars are distributed uniformly in Euclidean space (space satisfying the principles of Euclidean geometry).

The statistical studies of J.C. Kapteyn

The number N would increase with decreasing limiting apparent brightness f_0, because one is sampling, on average, larger volumes of space when one counts fainter sources. Kapteyn found that the number N increased less rapidly with decreasing f_0 than the hypothetical value $Af_0^{-3/2}$; this indicated to him that the solar system lay near the centre of a distribution of stars, which thinned in number with increasing distance from the centre. Moreover, Kapteyn determined that the rate of thinning was more rapid in certain directions than in others. This observation, in conjunction with other arguments that set the scale, led him in the first two decades of the 20th century to depict the Milky Way Galaxy (then confused with the entire universe) as a rather small, flattened stratum of stars and gaseous nebulas in which the number of stars decreased to 10 percent of their central value at a distance in the plane of about 8,500 light-years from the galactic centre.

In 1917 the American astronomer Harlow Shapley mounted a serious challenge to the Kapteyn universe. Shapley's study of the distances of globular clusters led him to conclude that their distribution centred on a point that lay in the direction of the constellation Sagittarius and at a distance that he estimated to be about 45,000 light-years (50 percent larger than the modern value). Shapley was able to determine the distance to the globulars through the calibration of the intrinsic brightnesses of some variable stars found in them. (Knowing the period of the light variations allowed Shapley to infer the average intrinsic brightness. A measurement of the average apparent brightness then allowed, from the $1/r^2$ law of brightness, a deduction of the distance r.) According to Shapley, the galactic system was much larger than Kapteyn's estimate. Moreover, the Sun was located not at its centre but rather at its radial outskirts (though close to the midplane of a flattened disk). Shapley's dethronement of the Sun from the centre of the stellar system has often been compared with Copernicus' dethronement of the Earth from the centre of the planetary system, but its largest astronomical impact rested with the enormous physical dimensions ascribed to the Galaxy. In 1920 a debate was arranged between Shapley and Heber D. Curtis to discuss this issue before the National Academy of Sciences in Washington, D.C.

The Shapley-Curtis debate

The debate also addressed a second controversy—the nature of the so-called spiral nebulas. Shapley and his adherents held that these objects were made up of diffuse gas and were therefore similar to the other gas clouds known within the confines of the Milky Way Galaxy. Curtis and others, by contrast, maintained that the spirals consisted of stars and were thus equivalent to independent galaxies coequal to the Galaxy. A parallel line of thought had been proposed earlier by the philosophers Immanuel Kant and Thomas Wright and by William Herschel. The renewed argument over the status of the spirals grew in part out of an important development that occurred around the turn of the 20th century: the astronomical incorporation of the methods of spectroscopy both to study the physical nature of celestial bodies and to obtain the component of their velocities along the line of sight. By analyzing the properties of spectral lines in the received light (*e.g.*, seeing if the lines were produced by absorption or emission and if the lines were broad or narrow), or by analyzing the gross colours of the observed object, astronomers learned to distinguish between ordinary stars and gaseous nebulas existing in the regions between stars. By measuring the displacement in wavelength of the spectral lines with respect to their laboratory counterparts and assuming the displacement to arise from the Doppler effect, they could deduce the velocity of recession (or approach). The spirals posed interpretative difficulties on all counts: they had spectral properties that were unlike either local collections of stars or gaseous nebulas (because of the unforeseen roles of dust and different populations of stars in the arms, disk, and central bulge of a spiral galaxy); and, as had been shown by the American astronomer Vesto Slipher, they generally possessed recession velocities that were enormous compared to those then known for any other astronomical object.

The formal debate between Shapley and Curtis ended inconclusively, but history has proved Shapley to be mostly right on the issue of the off-centre position of the solar system and the large scale of the Galaxy, and Curtis to be mostly right on the issue of the nature of the spirals as independent galaxies. As demonstrated in the work of the Swiss-born U.S. astronomer Robert J. Trumpler in 1930, Kapteyn (and Herschel) had been misled by the effects of the undiscovered but pervasive interstellar dust to think that the stars in the Milky Way thinned out with distance much more quickly than they actually do. The effect of interstellar dust was much less important for Shapley's studies because the globular clusters mostly lie well away from the plane of the Milky Way system.

The decisive piece of evidence concerning the extragalactic nature of the spirals was provided in 1923–24 by Hubble, who succeeded in resolving one field in the Andromeda galaxy (M31) into a collection of distinct stars. Some of the stars proved to be variables of a type similar to those found by Shapley in globular clusters. Measurements of the properties of these variables yielded estimates of their distances. As it turned out, the distance to M31 put it well outside the confines of even Shapley's huge model of the Galaxy, and M31 therefore must be an independent system of stars (and gas clouds).

Hubble's research on extragalactic systems

Hubble's findings inaugurated the era of extragalactic astronomy. He himself went on to classify the morphological types of the different galaxies he found: spirals, ellipticals, and irregulars. In 1926 he showed that, apart from a "zone of avoidance" (region characterized by an apparent absence of galaxies near the plane of the Milky Way caused by the obscuration of interstellar dust), the distribution of galaxies in space is close to uniform when averaged over sufficiently large scales, with no observable boundary or edge. The procedure was identical to that used by Kapteyn and Herschel, with galaxies replacing stars as the luminous sources. The difference was that this time the number count N was proportional to $f_0^{-3/2}$, to the limits of the original survey. Hubble's finding provided the empirical justification for the so-called cosmological principle, a term coined by the English mathematician and astrophysicist Edward A. Milne to describe the assumption that at any instant in time the universe is, in the large, homogeneous and isotropic—*i.e.*, statistically the same in every place and in every direction. This represented the ultimate triumph for the Copernican revolution.

Cosmological principle

It was also Hubble who interpreted and quantified Slipher's results on the large recessional velocities of galaxies—they correspond to a general overall expansion of the universe. The Hubble law, enunciated in 1929, marked a major turning point in modern thinking about the origin and evolution of the Cosmos. The announcement of cosmological expansion came at a time when scientists were beginning to grapple with the theoretical implications of the revolutions taking place in physics. In his theory of special relativity, formulated in 1905, Einstein had effected a union of space and time, one that fundamentally modified Newtonian perceptions of dynamics, allowing, for example, transformations between mass and energy. In his theory of general relativity, proposed in 1916, Einstein effected an even more remarkable union, one that fundamentally altered Newtonian perceptions of gravitation, allowing gravitation to be seen, not as a force, but as the dynamics of space-time. Taken together, the discoveries of Hubble and Einstein gave rise to a new worldview. The new cosmology gave empirical validation to the notion of a creation event; it assigned a numerical estimate for when the arrow of time first took flight; and it eventually led to the breathtaking idea that everything in the universe could have arisen from literally nothing (see below).

Components of the universe

PLANETARY SYSTEMS

Although it is commonly believed that planetary systems are plentiful in the universe, the only example known with certainty is the solar system. The solar system is conventionally taken to contain the Sun, the nine planets and their satellites, asteroids, comets, interplanetary dust, and interplanetary particles and fields largely associated

with the solar wind. Humanity's knowledge of these objects has expanded greatly owing to space exploration. Combined with centuries of intense astronomical observation and theoretical calculation, data transmitted by spacecraft have shed considerable light on the relation between the solar system and the rest of the universe, the problem of the origin of the Earth and the other planets, and the question of the likelihood of comparable planetary systems around other stars.

The Sun. At the centre of the solar system lies the Sun. Energetically and dynamically, it is the dominant influence in the solar system. The mass of the Sun can be measured from its gravitational pull on the planets and equals 2×10^{33} g (grams), 1,000 times more massive than Jupiter and 330,000 times more massive than the Earth. As a fraction of its mass, the atmospheric composition of the Sun is probably 72 percent hydrogen, 26 percent helium, and 2 percent elements heavier than hydrogen and helium. Because there is little mixing between the atmosphere and the deep interior (where nuclear reactions occur), this composition is believed to be the one that the Sun was born with. A gas with approximately the solar mix of elements is said to have cosmic abundances because a similar composition is found for most other stars as well as for the medium between the stars.

The mass and composition of the Sun

The observed rate of release of radiant energy by the Sun equals 3.86×10^{33} erg/sec (ergs per second). The particles of radiation (photons) stream more or less freely from a layer called the photosphere, which in the Sun is at a temperature of about 5,800 K (kelvins; 5,500° C or 10,000° F). The distribution of wavelengths is characteristic of a thermal body radiating at such a temperature; therefore, in accordance with Planck's law, it peaks in the yellow part of the visible spectrum. The solar luminosity is enormous, but it is much less than it would be if the photons in the hot interior of the Sun could also stream freely. However, the high opacity of the material regulates the actual outward progress of the photons to a slow stately diffusion. Indeed, the blockage of diffusive heat is so severe in the envelope of the Sun that its layers are unstable to the development of convection currents, which gives the atmosphere of the Sun a granular appearance.

The observed radius of the Sun equals 6.95×10^{10} cm and is understood to be the result of a balance of forces between the Sun's self-gravity and the pressure of its hot gases, which exist in a nearly fully ionized state (a plasma of positive ions and free electrons) in the deep interior. The plasma in the core of the Sun is compressed to temperatures (about 1.5×10^7 K) that are sufficient to provide a rate of thermonuclear reactions that just offsets the slow diffusive loss of radiative heat. Thus, the Sun constitutes a controlled fusion reactor capable of sustaining its present steady loss of radiant energy for a full 9×10^9 years before all of its initial supply of hydrogen fuel in the core has been converted into helium. From the radioactive dating of meteorites, it has been estimated that the solar system is 4.6×10^9 years old. If this is the age of the Sun, then it is roughly midway through the phase of stable core hydrogen fusion—*i.e.*, the "main-sequence" phase of stellar evolution.

Controlled hydrogen fusion in the Sun's core

The Sun is too opaque to electromagnetic radiation to allow a direct look at the nuclear reactions inferred to take place in its interior. Weakly interacting particles called neutrinos offer a better probe of such reactions because they fly relatively freely from the centre of the Sun. Attempts to measure solar neutrinos by means of radioactive chlorine techniques have found levels that are only about one-third the best theoretical predictions. One possible explanation supposes that neutrinos possess mass and can be converted to (oscillating) forms undetectable by conventional schemes during their passage through the dense solar plasma. Unfortunately, experiments using purified water or large amounts of gallium as the detecting medium have contributed conflicting data with respect to this interpretation.

An indirect line of evidence suggests that the source of the discrepancy may lie more with unknown neutrino physics than with uncertain solar models. Precise measurements of the small oscillations of the solar surface induced presumably by motions in the convection zone allow astronomers to study the properties of waves propagating through the Sun's interior in an analogous fashion to how earthquakes allow geologists to study the properties of the Earth's interior. These investigations reveal that the Sun behaves similarly, though not exactly, as the best theoretical solar models predict. They also show the Sun's radiative core to rotate at about the same angular speed as the mid-latitudes of the solar surface, too slow to have any of the anomalous mechanical or thermal effects that have sometimes been hypothesized for it.

The outermost layer of the Sun turns once every 25 days at the equator, once every 35 days at the poles. This differential rotation may couple with the Sun's convection zone to produce a dynamo action that amplifies magnetic fields. The basic idea is that magnetic fields carried upward (or downward) by convection currents are twisted and amplified by the differential rotation. "Ropes" of high field strength buoy to the surface where they pop out as loops into the corona of the Sun. The corona is an extended region containing very rarefied gas that lies above the photosphere and a transition region called the chromosphere; the temperature of the corona is about 2×10^6 K. The anchor points of the ropes of high magnetic flux in the photosphere correspond to sunspots, regions where the gas is cooler than the average photospheric temperature of 5,800 K. Thus, these spots appear relatively dark against the bright yellow background of the general photosphere.

Sunspots and other manifestations of magnetic activity

Sunspots appear, migrate about the solar surface, and disappear as the plasma to which they are anchored moves under the influence of rotation and convection. The average number of sunspots increases and decreases more or less regularly in an 11-year cycle; however, there have been prolonged minima in history. It has been proposed that these prolonged minima correlate with changing climate conditions on the Earth, although the precise mechanisms for effecting such changes remain unclear.

Other manifestations of magnetic activity arise because of the motion of the flux ropes. It is believed that flares occur on those occasions when two flux ropes of opposite polarity are pressed against each other, and the opposing magnetic fields annihilate in a catastrophic event of magnetic reconnection. The energy stored in the field is thought to go into accelerating fast particles (solar cosmic rays) and into heating the ambient gas, which, being rarefied, has very little heat capacity. Magnetic activity of this type may be what maintains the corona at much higher temperatures than the photosphere.

Pictures of the solar corona taken during the U.S.-manned Skylab missions (1973) showed that hot coronal gas trapped in closed loops of field lines becomes dense enough to emit appreciable amounts of X rays. In contrast, coronal holes lacking X-ray emission correspond to regions where the magnetic field is too weak to keep the gas trapped and the hot gas has burst open the magnetic-field configuration, expanding away from the surface of the Sun as part of a general solar wind.

The presence of a solar wind blowing through interplanetary space was first deduced from observations made during the 1950s of the ion tails of comets. With the advent of Earth-orbiting satellites, the particles and fields carried by the solar wind could be measured directly. When the wind blows past the Earth, it contains on average about five particles per cubic centimetre (mostly protons, the nuclei of hydrogen atoms) moving at about 500 km/sec (kilometres per second), but these numbers fluctuate greatly depending on the phase of the solar magnetic cycle and the presence or absence of recent flare activity.

Planets and their satellites. Clues as to how the planets were formed lie in the regularities of their orbital motions, their satellite systems, and their chemical compositions. Compared to their sizes, the separations of planets from each other are enormous; and, apart from a diffuse solar wind and minor debris, interplanetary space is remarkably empty. Thus, as a general rule, the planets have been well isolated dynamically and chemically since their birth, and the present configuration of the solar system provides hints of the initial conditions, in spite of the more than 4×10^9 years of subsequent evolution.

With the exception of Mercury and Pluto, the orbits of the planets are all nearly circular; they lie within a few degrees of the same plane; and they have the same direct sense of revolution as the rotation of the Sun. Since these facts were first noted, they have suggested to philosophers and scientists such as Kant and Pierre-Simon Laplace of France that the planets of the solar system must have originally formed from a flat nebular disk that revolved about the primitive Sun. The exceptions, Mercury and Pluto, are not troublesome; they both suffer strong resonant interactions with other bodies that may have considerably modified their original orbital characteristics.

Differences between the terrestrial and Jovian planets

In the inner planetary system where the terrestrial planets—Mercury, Venus, Earth, and Mars—reside, the distance between successive planets is relatively small in comparison with the outer planetary system where the Jovian planets—Jupiter, Saturn, Uranus, and Neptune—reside. Moreover, the terrestrial planets are small and rocky or ironlike, while the Jovian planets (also called the giant planets) are large and gaseous or icy. Neither the terrestrial nor the Jovian planets exhibit the chemical elements in their cosmic proportions, but the latter, particularly Jupiter and Saturn, approach these proportions to a much closer degree. This implies that the process of planet building, unlike the mechanism of star formation, probably involves forces other than just gravity, for gravitation is universal and does not distinguish between different elements if they are in a gaseous form. Condensation (*i.e.*, the separation of solid phases of matter from gaseous phases if the temperature drops to sufficiently low values) suggests itself as an important process.

From this point of view, the terrestrial planets have managed only to gather into their bodies mostly materials containing elements heavier than hydrogen and helium—materials such as silicate rocks and metallic iron or nickel, which can condense as solids from a gaseous phase even at relatively high temperatures (between 1,200 and 2,000 K). In contrast, Uranus and Neptune have not only accumulated rocky and metallic compounds but also ices of water, ammonia, and methane, which can condense from nebular gas only at much lower temperatures (between 100 and 200 K). Jupiter and Saturn succeeded additionally in capturing substantial amounts of hydrogen and helium (in their envelopes). Since hydrogen and helium at plausible nebular pressures do not solidify unless the temperature is lower than even in the coldest regions of interstellar space, this suggests that in the two largest planets of the solar system gravitation did play a role in the direct acquisition of massive amounts of these gases.

Pluto, which is small and icy and orbits farthest from the Sun, is not readily classifiable in the scheme outlined above. The discrepancy is not disruptive, however, because Pluto, discovered in 1930, and its moon, Charon, discovered in 1978, are relatively minor bodies similar in composition to the comets.

The terrestrial and Jovian planets possess other systematic differences: the former generally have no rings or satellites, while the latter each have a set of rings and many satellites. Here, Earth and Mars are exceptions to the rule. Earth has of course one satellite, the Moon; Mars has two, Phobos and Deimos. Of these exceptions, the more difficult case to explain has long remained the Moon because it is an unusually large object for a satellite. Indeed, the Moon is only somewhat smaller than the largest and most massive satellites in the solar system: Jupiter's Ganymede, Saturn's Titan, and Neptune's Triton. In comparison, Phobos and Deimos are tiny objects that may well have been captured after Mars had already formed.

Regular and irregular satellites

The satellite and ring systems of the giant planets, particularly those of Jupiter and Saturn, resemble miniature planetary systems. As an analogy, one may say that moons and rings are to the giant planets what the planets and the asteroid belt are to the Sun. The moons of the giant planets can be classified as either regular or irregular. The regular satellites have nearly circular orbits lying in the same plane as the equator of the parent planet and revolve in the same direction as its rotation. The irregular satellites violate one or more of the above rules. In addition, they generally tend to be small bodies and to lie at large distances from the central planet. The regular satellites may have formed from protoplanetary disks that encircled the planet in the same manner as a protostellar disk encircled the Sun in the nebular hypothesis. The most likely explanation for the irregular satellites is that they are captured bodies.

The thin flat rings that encircle Jupiter, Saturn, Uranus, and Neptune are composed of innumerable small solid bodies. Each piece of the ring is in a nearly perfect circular orbit about the central planet. Theory suggests that noncircular motions are damped by mutual inelastic collisions of the particulate matter to very small values. These collisions would have led to gradual agglomeration into larger bodies had the rings not lain in such close proximity to the planet (*i.e.*, within the Roche limit). The strong tidal forces that exist inside the Roche limit of a planet are believed to be capable of tearing apart loosely bound aggregates of particulate matter and thereby preventing their agglomeration into moons. It is unclear, however, whether planetary rings are the natural debris left over from an earlier period of satellite formation in a protoplanetary disk that extended almost to the planet's surface or whether they arose from the more recent breakup and erosion (by continual collisions and by micrometeoroid bombardment) of some larger parent body. There does exist some evidence from dynamic studies of the gravitational interactions of the rings and satellites of Saturn that the rings may be appreciably younger than the solar system in general.

Asteroids, meteoroids, comets, and interplanetary dust. In addition to the Sun and its wind and the nine planets and their satellites, the solar system contains a large number of minor bodies. The most conspicuous of these are the asteroids and comets. Smaller bodies also exist—meteoroids, micrometeoroids, and interplanetary dust—but these probably are fragments of the larger asteroids and comets. Indeed, there is a continuous distribution of minor bodies in the solar system, from dust particles with radii of only a fraction of a micrometre to asteroids (or minor planets) with radii of several hundred kilometres.

Asteroid sizes

Asteroids are rocky or iron-bearing bodies found orbiting the Sun in great numbers in a belt between Mars and Jupiter. Nearly all of the total mass of the asteroids, about 10^{-3} that of the Earth, is contained in the largest examples such as Ceres, Pallas, and Vesta, but the largest numbers have radii of one to 10 kilometres (the lower limit being more a matter of nomenclature than of measurement). A few bodies, as, for example, Chiron, lie outside the belt between Mars and Jupiter. The exceptions, however, are relatively rare. The theoretical understanding of this observational result lies in computer simulations that show that an asteroid placed almost anywhere else in the solar system besides the known asteroid belt would be unstable owing to gravitational perturbations by the planets. If the early solar system were littered with asteroid-sized bodies, then the emergence of the planets would have swept interplanetary space relatively clean except for the debris that happened to have orbits fit for survival.

Meteoroids are chunks of asteroids or comets that have Earth-crossing orbits. One theory for the production of meteoroids has them originating from the shattering of two asteroids that collide violently in space. Some of the pieces may subsequently suffer resonant interactions with Jupiter, which throw them in 10,000 to 100,000 years into elongated Earth-crossing orbits. A meteoroid entering the Earth's atmosphere will heat up during the passage and become a meteor, a fiery "shooting star." If the mass of the meteor exceeds one kilogram, it can survive the flight and land on the ground as a meteorite. Meteorites come in three basic compositions: stones, stony irons, and irons. Radioactive dating of meteorites establishes that they have a narrow range of ages. The time since their parent bodies first solidified equals about 4.6×10^9 years, which yields the conventional estimate for the age of the entire solar system.

The cratering records on the airless (and therefore erosion-free) Moon and Mercury are consistent with a very heavy period of meteoritic impacts during the first several hundred million years of the history of the solar

system, with the bombardment tailing off dramatically about 4×10^9 years ago. This picture suggests that primitive asteroids and meteoroids may have been the building blocks ("planetesimals") of the terrestrial planets (and perhaps also the cores of the giant planets) and that the present-day asteroids failed to be gathered into another full-fledged planet because their noncircular velocities are so high (probably owing to the past near-resonant action of Jupiter's gravitational perturbations) as to cause them generally to shatter rather than to agglomerate when they collide.

Comets also are cosmic debris, probably planetesimals that originally resided in the vicinity of the orbits of Uranus and Neptune rather than in the warmer regions of the asteroid belt. Thus, the nuclei of comets are icy balls of frozen water, methane, and ammonia, mixed with small pieces of rock and dust, rather than the largely volatile-free stones and irons that typify asteroids. In the most popular theory, icy planetesimals in the primitive solar nebula that wandered close to Uranus or Neptune but not close enough to be captured by them were flung to great distances from the Sun, some to be lost from the solar system while others populated what was to become a great cloud of cometary bodies, perhaps 10 trillion in number. Such a cloud was first hypothesized by the Dutch astronomer Jan Hendrik Oort.

Oort cloud

In the original version of the theory, the Oort cloud extended tens of thousands of times farther from the Sun than the Earth, a significant fraction of the way to the nearest stars. Random encounters with passing stars would periodically throw some of the comets into new orbits, plunging them back toward the heart of the solar system. As a comet nears the Sun, the ices begin to evaporate, loosening the trapped dust and forming a large coma that completely surrounds the small nucleus, which is the ultimate source of all the material. The solar wind blows back the evaporating gas into an ion tail, and radiation pressure pushes back the small particulate solids into a dust tail. Each solid particle is now an independently orbiting satellite of the Sun, and the accumulation of countless such passages by many comets contributes to the total quantity of dust particles and micrometeoroids found in interplanetary space.

The total mass contained in all the comets is highly uncertain. Modern estimates range from 1 to 100 Earth masses. Part of the uncertainty concerns the reality of a hypothesized massive "inner Oort cloud"—or "Kuiper belt" (if the distribution is flattened)—of comets that would exist at distances from the Sun 40 to 10,000 times that of the orbit of the Earth. At such locations, the comets would not be much perturbed by typical passing stars nor by the gravity of the planets of the solar system, and the comets could reside in the inner cloud or belt for long periods of time without detection. It has been speculated, however, that a rare close passage by another star (possibly an undetected companion of the Sun) may send a shower of such comets streaming toward the inner solar system. If enough large cometary nuclei in such showers happen to strike the Earth, the clouds of dust and ash that they would raise might be sufficient to trigger mass biological extinctions. An event of this kind appears especially promising for explaining the relatively sudden disappearance of the dinosaurs from the Earth.

Origin of the solar system. Modern versions of the nebular hypothesis all begin with the collapse of a rotating interstellar cloud that is destined to form the solar system. The tendency to conserve angular momentum causes the falling gas to spin faster and flatten, eventually forming a central concentration (protosun) surrounded by a rotating disk of matter. Detailed calculations show that there may be a prolonged phase of infall that continues to build up a disk of increasing mass and size. There also may be some accretion of the material in the disk onto the star, the process transferring mass inward and angular momentum outward, which helps to explain why the Sun presently contains 99.9 percent of the total mass of the solar system but only 2 percent of the total angular momentum.

Nebular hypothesis

Because the chemical compositions of the planets as a function of increasing radial distance from the Sun follow a pattern that corresponds to sequential condensation from a gaseous state, cosmochemists originally postulated, for simplicity, that the solar nebula began in a hot and purely gaseous state. Small pieces of solids were then imagined to have condensed from the gas in the disk as the latter slowly cooled from high temperatures, with the coolest final temperatures being reached at the greatest distance from the centre. The process is akin to soot forming out of a smoking candle flame. Astronomical observations, however, show that dust grains of approximately the correct composition already exist in the interstellar medium, and theoretical calculations indicate that the refractory cores of the grains would survive introduction into most of the primitive solar nebula. The icy mantles that coat the grain cores would, however, be evaporated away in the inner solar system. It is probable, therefore, that the systematics of the observed planetary compositions reflect not a condensation sequence but rather an evaporation sequence.

In any case, whether the dust particles form by chemical condensation from the nebular gas or exist from the start, there seems little doubt that they would grow rapidly by various agglomeration processes and dissipatively settle into a thin layer of particulate matter in the midplane of the disk. Planetesimals of the sizes of asteroids and the nuclei of comets accumulate in this thin layer and further grow by gravitational processes into full-sized planets. The formation of the planets under these dissipative circumstances would explain why their orbits are nearly coplanar and circular.

Insofar as the planets first grow by the accumulation of solids, it is interesting to note that observations indicate all four Jovian planets to have rocky and icy cores containing 15–25 Earth masses. In addition to such cores, Jupiter and Saturn have hydrogen and helium envelopes amounting to about 300 and 70 Earth masses, respectively. This suggests, as theoretical calculations bear out, that 15–25 Earth masses represents a critical mass above which a growing planet in the solar nebula will begin to gravitationally gather nebular gas faster than it will accumulate solids. Indeed, once a protoplanet becomes massive enough, it can efficiently eject solid bodies as well as capture them. (The ones catapulted out by Jupiter and Saturn are likely to escape the system altogether.) In this way did Jupiter and Saturn become large and grow to occupy large areas.

Process of planetary growth

Why Uranus and Neptune did not also gather massive gaseous envelopes is somewhat of a mystery. One possible theory is that, at the distances of Uranus and Neptune in the solar nebula, energetic radiation from the young Sun can dissociate hydrogen molecules and ionize the resultant atoms, heating the surface layers strongly enough (to about 10,000 K) to disperse the nebular gas over a period of about 10^7 years. The full accumulation of the planetary cores of Uranus and Neptune probably took longer, and therefore their formation occurred in a relatively gas-free environment.

The growth of Pluto through the aggregation of many millions of cometlike bodies may have been limited by having to occur at the outermost fringes of the primitive solar nebula. Its moon, Charon, may have resulted either through fission of a rapidly rotating common parent body or through a late encounter and capture. Icy planetesimals that had close but noncolliding encounters with Uranus and Neptune either were thrown into the Sun (or into other planets) or now populate the Oort cloud of comets.

Interior to Jupiter the planets are all small. A plausible explanation follows from the observation that the solar nebula inside Jupiter's orbit may have been too hot to allow methane, ammonia, and water to exist in solid form. Computer simulations by the American geophysicist George Wetherill show that, restricted to the accumulation of only the rarer rocks and irons, the rapid runaway growth of planetesimals to embryos in the inner solar system stalls at masses comparable to the Moon's. Once a few hundred embryos of Moon-like masses have accumulated most of the solid matter in their immediate "feeding" zones, it takes them more than 10^8 years gravitationally to pump up each other's eccentricities and aggregate through orbit crossings into four terrestrial planets.

Formation of the terrestrial planets

A long duration for the formation of the terrestrial planets

(supported by crater counts that indicate a prolonged period of bombardment extending over some 5×10^8 years) suggests that Jupiter may have finished forming before the terrestrial planets did. A massive body at Jupiter's orbit may have then so stirred up the orbits of the planetesimals in the asteroid belt as to have prevented them from accumulating into a large body (see above). A fully formed Jupiter also may have stunted the growth of nearby Mars, explaining why Mars is so much smaller a terrestrial planet than either Venus or Earth.

The giant planets may also have sent fairly large bodies careening through the early solar system. In one version of the event, by the American astrophysicist Alastair G.W. Cameron and coworkers, a Mars-sized body crashed obliquely into the primitive Earth. The molten core of the intruder sank to the centre of the molten proto-Earth, but mantle material from both bodies went into orbit and eventually reaccreted into the Moon. The formation of the Moon from rocky substances would then explain why the lunar landings found the Moon to be much poorer in iron than the Earth.

A similar scenario purports to explain a compositional peculiarity in Mercury. A massive body from the asteroid belt sent close to the Sun would acquire such large velocities that on collision with Mercury it would splash off not only its own rocky mantle but much of Mercury's as well. An event of this kind might explain why Mercury has such a small rocky envelope in relation to its iron-nickel core when compared with the same features in Venus, Earth, and Mars.

Giant impacts would also add a chaotic element to the acquisition of planetary spins. Perhaps this accounts for the fact that, while most of the equators of the planets lie in roughly the same plane as their orbits about the Sun, Venus spins in a retrograde sense, whereas Uranus' spin axis is tilted over on its side. In reconstructing the details of the formation of the solar system, astronomers work under the handicap of not knowing whether certain special features arise as a general rule or as an exceptional circumstance.

Extrasolar planetary systems. The astronomical detection of planetary systems around other stars would help enormously to loosen the restrictions imposed by being able to study only one example. Although claims have been made for the discovery of planets around pulsars (spinning magnetized neutron stars), relevant comparisons can be made for the solar system only if the central object is a normal star. For such cases, the task of detection is made difficult by the glare of the star. At least two independent lines of evidence exist, however, that relate indirectly to the existence of extrasolar planetary systems.

First, it is known from studies of gas clouds where stars are currently forming in the Galaxy that such regions generally rotate too quickly to collapse to a single normal star without any companions. Investigators know of many examples where the excess angular momentum has apparently been absorbed in the birth of a nearby orbiting star; indeed, binary stars are known to be the most common outcome of the star-formation process. It is, nevertheless, encouraging that infrared searches for faint companions around apparently single stars have found a few candidates for objects that lie intermediate to the least massive normal star and a giant planet such as Jupiter.

Detection of nebular disks around young stars

Second, infrared images taken from Earth-orbiting and ground-based telescopes have found flattened distributions of particulate solids encircling young stars that resemble the type of dusty nebular disk long hypothesized for the origin of the solar system. In a few cases, there have also been detections, from spectroscopic observations at millimetre and near-infrared wavelengths, of gaseous molecular material coextant with the solid particulates. These observations lend strong support to the view that the creation of planetary systems is likely to be a common by-product of the process of star formation.

STARS AND THE CHEMICAL ELEMENTS

Stars are the great factories of the universe. They gradually transform the raw material that emerged from the big bang into an array of versatile chemical elements that makes possible the birth of planets and their inhabitants. The empirical evidence for the vital role that stars play in nucleosynthesis lies in the spectroscopic analysis of the atmospheric compositions of different generations of stars. The oldest stars, which belong to globular clusters, possess very little in the way of elements heavier than hydrogen and helium—in some cases, less than 1 percent of the value possessed by the Sun. On the other hand, the youngest stars, which have ages on the order of 10^6 years, have heavy elements in even slightly greater abundance than the Sun. Astronomers give these results explicit recognition by designating stars with high heavy-element abundance as Population I stars; those with low heavy-element abundance are said to be Population II stars.

Synthesis of heavy elements in stellar interiors

The accepted interpretation of the abundance differences of Populations I and II is that stars synthesize heavy elements in their interiors. In the process of dying, some stars spew great quantities of this processed material into the gas clouds occupying the regions between the stars. The enriched matter then becomes incorporated into a new generation of forming stars, each successive generation having on average a greater proportion of heavy elements (and helium) than the last. During the 20th century astronomers have obtained considerable insight into why these processes should be the natural outcome of the structure and evolution of stars.

Main-sequence structure of the stars. The same general principles that determine the structure of the Sun apply more broadly to all normal stars: (1) Hydrostatic equilibrium—for a star to be mechanically in equilibrium, the internal pressure must balance the weight of the material on top. (2) Energy transfer—photons diffusively carry energy outward from a hot interior; if the luminosity to be carried exceeds the capacity of photon diffusion, convection ensues. (3) Energy balance—for a star to be thermally in equilibrium, the energy carried outward by radiative diffusion or convection must be balanced by an equal release of nuclear energy; if the rate of thermonuclear fusion is inadequate, gravitational contraction of the central regions will result, usually accompanied by an expansion of the outer layers.

Most of the time of the luminous stages of a star's life is spent on the main sequence, when it stably fuses hydrogen into helium in its core. The fusion process in a star with mass slightly greater than one solar mass is somewhat different from that in a star of one solar mass or less. In high-mass stars, hydrogen fusion occurs at high temperatures using preexisting nuclei of carbon and nitrogen as catalysts and, in the process, converting much of the carbon into nitrogen. In low-mass stars, hydrogen fusion occurs by direct combination of the hydrogen nuclei or their reaction products. The end product, however, is the same: the conversion of four hydrogen nuclei into one helium nucleus, with the release of the nuclear binding energy as a source of heat for the star.

The time that a low-mass star spends on the main sequence differs drastically from that of a high-mass star. On the main sequence, a low-mass star spends its nuclear resource thriftily; a high-mass star, prodigiously. Hence, core hydrogen exhaustion for low-mass stars is delayed in comparison to high-mass stars. The main-sequence lifetime of a star half as massive as the Sun is about 3×10^{10} years, whereas that of a star of 50 solar masses would be roughly 3×10^6 years.

Since the lifetime of a high-mass star is much less than the age of the Galaxy (roughly 10^{10} years) and since such stars exist during the present epoch in the Galaxy, the formation of high-mass stars must be an ongoing process. This is borne out by observations of the Galaxy and external galaxies, where bright blue stars are always found near giant clouds of gas and dust—the sites of both high-mass and low-mass star formation.

Study of star clusters

One of the most important tests for the theory of stellar structure and evolution comes from the examination of star clusters. Star clusters are gravitationally bound stellar groups that occur in two basic types: globular clusters, which typically are rich systems containing perhaps one million members distributed in a compact spherical volume with a strong concentration toward the centre, and

open clusters, which typically are poor systems containing 1,000 members or fewer distributed loosely throughout an irregular volume. Globular cluster stars belong to Population II, while open cluster stars belong to Population I (see GALAXIES).

All astronomical observations of a star cluster indicate that its members formed from the same parent cloud. Thus, the stars in a cluster have the same age and the same initial compositions; the only notable difference among them is their masses. Since stars of different masses evolve at different rates, it should be possible to see a progression of evolutionary states as stars of increasing mass are considered. The effect is indeed seen, and the comparison of theoretical predictions with astronomical observations of star clusters yields one of the most satisfactory success stories of modern astrophysics. Such studies allow estimates of the ages of star clusters. The oldest turn out to be the globular clusters; they have ages estimated by various investigators between 1×10^{10} and 1.8×10^{10} years. Within the errors of the determinations, the ages of globulars are consistent with the expansion age of the universe—approximately 1.5×10^{10} years—obtained from Hubble's law. Thus, the globular cluster stars in the Galaxy must constitute some of the oldest stars in the Cosmos.

Ages of star clusters

On the main sequence, a high-mass star is not only much more luminous than a low-mass star, but it also appears much bluer because its surface temperature is a few tens of thousands degrees instead of a few thousand degrees. The difference in surface temperature manifests itself not only in broadband colours but also in the pattern of atomic absorption lines that appear in spectroscopic diagnostics of the star. The Latin letters OBAFGKM are used to classify stars of different spectral types, with O stars having the hottest surface temperatures and M stars the coolest. The Sun is a G star. This classification scheme applies to all stars, not merely to those on the main sequence. To distinguish stars on the main sequence from those in different evolutionary states, astronomers introduced the concept of luminosity class. These categories are designated by Roman numerals from I to V, with I corresponding to supergiants and V to dwarfs. Main-sequence stars are dwarfs because stars have their smallest sizes as luminous objects when they shine by hydrogen fusion in the core, and a small star (dwarf or subgiant) of a given spectral type—*i.e.,* surface temperature—radiates less than a large star (giant or bright giant or supergiant) of the same spectral type. Stars smaller than main-sequence stars are known (white dwarfs, neutron stars, or black holes), but they are very faint and are not normal stars and so are not assigned classifications in the normal scheme.

Predominance of main-sequence stars

About 90 percent of the luminous stars in a galaxy at any given time are on the main sequence. Most of the mass of a galaxy is contained in low-mass stars, but the small number of high-mass stars contributes a disproportionate fraction of the total light, especially at blue wavelengths. Most of the light at red wavelengths comes from evolved stars because all stars tend to become redder as they evolve from the main sequence (*i.e.,* as their surfaces expand and cool). In addition, low-mass stars also tend to brighten as they age.

The end states of stars. The attempt of stars to achieve mechanical and thermal balance during their luminous lifetime leads inexorably to their demise. The fundamental reason is simple, at least in outline. Because a normal star is composed of ordinary compressible gases, it has to be hot inside to sustain the thermal pressure that resists the inward pull of its self-gravity. On the other hand, interstellar space is dark and cold; radiant heat flows continuously from the star to the universe. The nuclear reserves that offset this steady drain are finite and can only offer temporary respites. When they have run out, the star must die.

Astronomers believe that there are four possible end states for a star: (1) There may occur a violent explosion that completely overcomes self-gravity and disperses all constituent matter to interstellar space; this would leave nothing behind as the stellar remnant. (2) The free electrons in the core of the star may finally become so densely packed that quantum effects allow them to exert enough pressure (termed electron-degeneracy pressure; see below) to support the star even at zero temperature; this would leave behind a white dwarf as the stellar remnant. (3) If the mass of the core exceeds the maximum value—the Chandrasekhar limit of 1.4 solar masses—allowed for a white dwarf, the compression of the stellar matter may finally be stopped at nuclear densities; this would leave behind a neutron star. (4) If the mass of the core is so large that even nuclear forces are incapable of supporting the star against its self-gravity, the gravitational collapse of the star may continue to a highly singular state at the centre; this would leave behind a black hole.

White dwarfs, neutron stars, and black holes

Observations of star clusters and highly evolved objects suggest that stars initially less massive than about eight solar masses are able to lose enough of their envelopes in the final stages of normal stellar evolution that their burnt-out cores fall below the Chandrasekhar limit, resulting in a white dwarf remnant. Theoretical calculations are able to reproduce this result if empirical envelope-mass loss rates are adopted for the later stages of the evolution. In the range of 8 to 25 solar masses, the star is believed to suffer an iron-core collapse, giving an implosion of the central regions to form a neutron star and an expulsion of the envelope in a supernova explosion. Above 25 solar masses or so, the situation remains somewhat confused. Some stars may lose so much mass in powerful winds that their hydrogen envelopes are stripped clean. When they finally explode, they do so as supernovas of what astronomers term type Ib or Ic. In other stars, the energy deposited by neutrino emission (see below) may not suffice to blow off the outer layers, and the entire star collapses inward to form a black hole.
